4. Facilitating conditions: The availability and accessibility of necessary resources (such as training and support) that enable an individual to use a technology.

Table 1 shows the questions used in the project in relation to each construct. As part of the project, if required, parents were supplied with weighing scales and an oxygen saturation monitor to report their child's weight and oxygen saturation at each RC and for use as required.

Table . Project-specific questions used in relation to each construct of the Unified Theory of Acceptance and Use of Technology questionnaire.

Construct	Measure item
Performance expectance	• Using Pexip speeds up my child's care • Using Pexip makes it easier to manage my child's care • Pexip will increase the quality of my child's care • I find Pexip useful for my child's care
Effort expectancy	• Learning to operate Pexip has been easy for me • I find Pexip flexible • I find Pexip easy to use • Using Pexip takes too much time • Using Pexip is complicated • Learning to use Pexip has been easy for me • Overall, I believe that Pexip is easy to use
Social influence	• People who are important to me think that I should use Pexip • The hospital has helped me to use Pexip • The hospital has supported me to use Pexip
Facilitating conditions	• I have control over using Pexip • There is someone available to help me with any difficulties I have with Pexip • Using Pexip fits well with my and my child's routine

Parent Interviews

Parents were invited to discuss their experience of using the videoconferencing application for their children's routine RCs. Interviews were conducted via WhatsApp by 2 members of the research team (MS and JEMM) using open and closed questions. WhatsApp was used to ensure parents skills and experience relating to the use of the videoconferencing application was strictly confined to the RCs. All interviews were audio recorded and carried out within 1 week following T1, T2, and T3 and at parents' discretion. Training in the use of video calls was not required, as all parents were experienced users.

Interviews were analyzed using Braun and Clarke's Reflexive Thematic Analysis method [34]. This approach was considered the most suitable to explore the lived experiences of using videoconferencing and add meaning to the findings from the UTAUT questionnaire.

Statistical Analysis

Descriptives statistics were generated. Frequencies, means, and SDs were generated according to variable type. Cronbach α's were generated for constructs (Table 1). Using repeated measures analysis of variance, the pre- and postintervention UTAUT questionnaire data points were analyzed.

Ethical Considerations

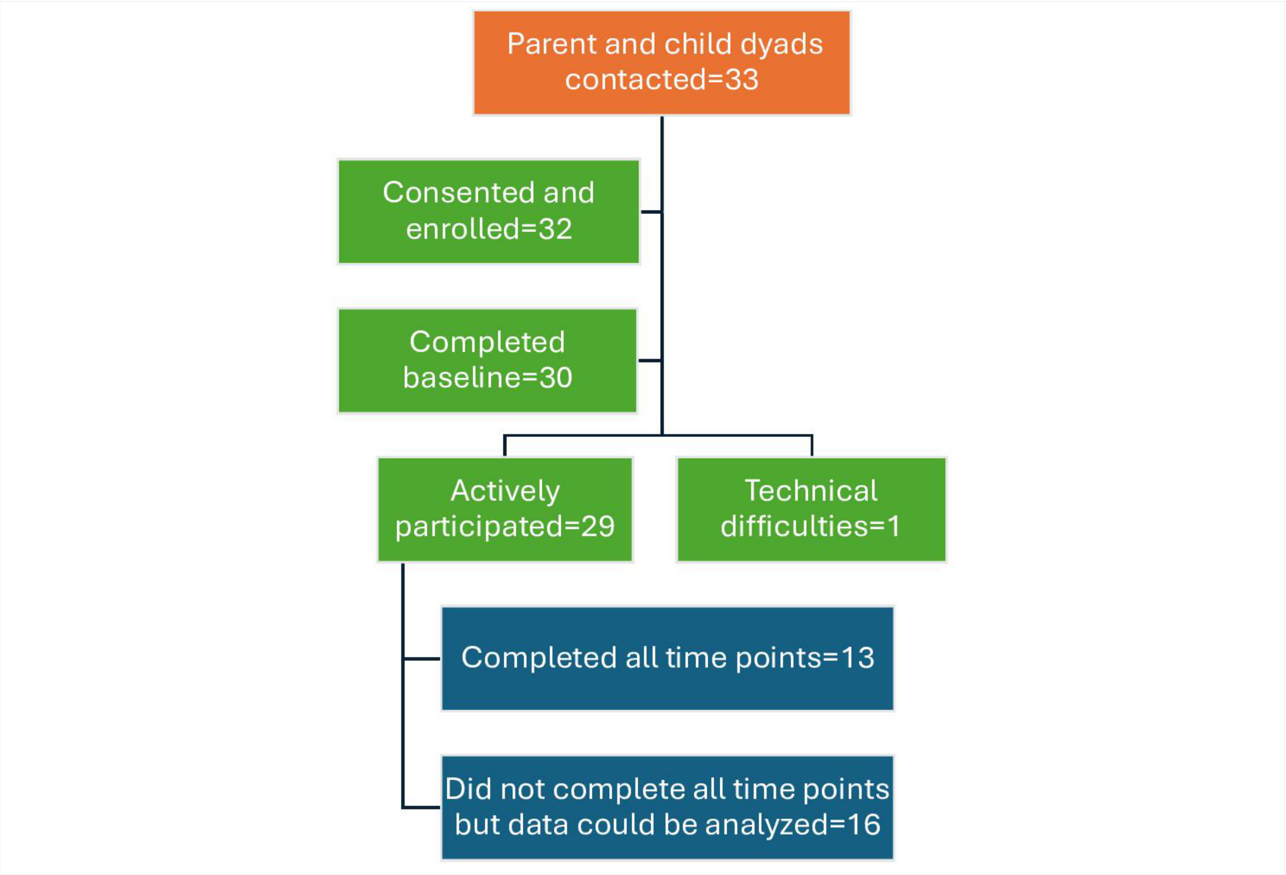
Ethical approval was granted by East of England—Cambridge South Research Ethics Committee on September 23, 2020 (20/EE/0190) and Confirmation and Capability at Belfast Health and Social Care Trust was granted on October 6, 2020 (HSC Trust reference: 20028MS-SW). All parents and children had the choice to opt out of the study or leave the study at any time after providing informed consent, without the need to provide a reason and without otherwise affecting the medical care children received. All quantitative data collected were anonymized, and all qualitative data were deidentified before analysis. In this study, no compensation was provided to parents or children for their participation.

Results

Recruitment

The parents of 33 children were approached while their child was an inpatient at the RBHSC or a regional general hospital (n=21) or was attending an outpatient clinic (n=12), and 32 child and parent dyads provided written consent and were enrolled in the project. For 1 child, both parents actively participated in the project (participants 1004a and 1004b). In total, 30 dyads (31 parents) completed the baseline questionnaire, and 1 dropped out due to technical issues. Therefore, 29 child and parent dyads completed the project, with 13 completing all time points. Figure 1 demonstrates the flow of participants throughout the project.

Figure 1. Recruitment and retention flowchart for the pediatric cardiology remote consultation project.



Participant Characteristics

Of the parents who completed the project, 93% (n=28) were mothers, 11 of whom were first-time mothers, and 6 (54.5%) of these received their child's diagnosis post birth. None of the parents had an STAI score above 65. Of the 29 children participating, 38% (n=11) were female. In total, 23 children were aged younger than 3 months at enrollment (mean 37.62, SD 32.5 d), 5 were aged between 3 months and 1 year, and 1 child was over 34 months (1052 d). Families resided across all 5 Health and Social Care Trusts in NI at a maximum distance of 133.1 km from the RBHSC, equating to a 3- to 4-hour round trip (Multimedia Appendix 2). Table 2 shows the demographic characteristics of the participating parents and children. The participating children had a range of complex conditions requiring surgery within the first 6 months of life (Table 3). In total, 17 children had a surgery or procedure during their participation. Half of the children had a coexisting congenital anomaly, with Down syndrome being the most common (n=7, 24%).

Table . Demographics of the parents (n=30) and children (n=29) who completed the pediatric cardiology remote consultation project.

Characteristics		Participants
Gender (parents), n		
	Female	28
	Male	2
Age of parents (years), mean (range; SD)		32.9 (20 - 47; 5.5)
Education level of parents, n		
	No qualifications	0
	High school	6
	College	8
	Apprenticeship	2
	Undergraduate	6
	Postgraduate	8
Distance from home to Royal Belfast Hospital for Sick Children (km), mean (range; SD)		49.3 (2.3 - 133.1; 39.61)
Timing of child’s diagnosis, n		
	Antenatal	13
	Postnatal	16
Sex (children), n		
	Female	11
	Male	18
Age of children at enrollment (days), mean (range; SD)		98 (4 - 1052; 191.14)

Table . Conditions of children included in the pediatric cardiology remote consultation project.

Primary cardiac diagnosis	Cases (n=29), n (%)
Tetralogy of Fallot	7 (24)
Atrioventricular septal defect	5 (17)
Ventricular septal defect	4 (14)
Shone complex (days)	2 (7)
Dysplastic tricuspid valve	2 (7)
Coarctation of aorta	2 (7)
Complex single ventricle pathology	2 (7)
Transposition of the great arteries	1 (3)
Patent ductus arteriosus	1 (3)
Total anomalous pulmonary venous drainage	1 (3)
Cardiomyopathy with severe outflow obstruction	1 (3)
Restrictive and hypertrophic cardiomyopathy	1 (3)

Videoconferencing Enabled Remote Consultations

In total, 201 (range 1 - 8) RCs were completed as part of the project, with the first RC (T1) taking place at a mean duration of 25.07 (SD 17.74; range 0 - 57) days following discharge.

Data gathered at baseline demonstrated that 23% (7/30) of parents were somewhat or not very experienced in the use of technology (Table 4). However, following their first experience using videoconferencing for RCs (T1) 83% (20/24) agreed that it was easy to use. At T3, 100% (n=17) agreed it was easy to use.

Table . Participating parents' (n=30) self-reported level of experience of using technology at baseline (T0).

What is your level of experience in using the following	Not very experienced or somewhat experienced, n (%)	Neither experienced or inexperienced, n (%)	Quite experienced or very experienced, n (%)
Electronic devices such as smart phones and tablets	6 (20)	3 (10)	21 (70)
Computers	9 (30)	3 (10)	18 (60)
Talking to others on video calls	8 (26.7)	3 (10)	19 (63.3)
Technology overall	7 (23.3)	4 (13.3)	19 (63.3)

A total of 63 post-RC questionnaires out of a possible 90 were completed, giving a 70% completion rate. On these occasions, 100% (n=29) of parents agreed or strongly agreed with the question "The problems and or questions I had were answered to my satisfaction during the videoconference."

During 97% (61/63) of the RCs, parents used smartphones, including iPhone (n=24, 38%) or Android (n=37, 59%) smartphones. For 2 calls, an iPod was used. For 21% (13/63) of the calls, an audio problem was reported; these were resolved on most occasions by hanging up and reconnecting or performing a forced stop of the videoconferencing application and reconnecting. No parents reported an issue with the video quality of the RCs.

Technology Acceptance

The Cronbach α coefficients for the constructs in the UTAUT adapted for this study were 0.94 for performance expectancy, 0.91 for effort expectancy, 0.76 for social influence, and 0.77 for facilitating conditions, suggesting that the questions presented in the questionnaire were correlated and measured the same concepts.

Across the 4 constructs of the UTAUT, results showed a nonstatistically significant trend upward (n=14). Therefore, this suggests that as parents became more experienced at using videoconferencing for RCs their beliefs in its ease of use and their acceptance of it were enhanced.

Parents' Experiences

A total of 41 interviews were conducted via video call with 26/30 parents (Table 5) to assess parents' experiences. The total duration of interviews analyzed was 19 hours and 56 minutes. Further, 1 parent declined to take part in any interview, and 4 could not take any calls due to their baby being admitted to hospital, work commitments, and scheduling issues. In total, 5 participants enrolled in the project completed all 3 interviews. Parents did the interviews most often with their child; alone; or with other family members present, including their child's other parent, sibling, or grandparent. On average, interviews lasted 20 minutes. Data saturation was achieved.

Table . Number of parents (n=30) completing video call interviews on the pediatric cardiology remote consultation project.

Video call interviews	Parents completing interviews (n)
No interview	5
1 interview	14
2 interviews	6
3 interviews	5

Parents reported their main concerns discussed at each RC were feeding, including breast feeding; weight; medications; surgery timing; surgical wounds; and details about their child's condition. Further, 1 parent reported that they asked about childhood vaccinations and about taking their baby swimming. At T1 (n=23) and T2 (n=20), 100% of parents agreed their problems or questions were answered to their satisfaction during the RC, and 94% (15/16) of parents agreed at T3. Following the RCs, parents agreed it had been beneficial at T1 (19/23, 83%), T2 (20/21, 95%), and T3 (13/17, 76.5%).

An experienced member of the pediatric cardiology team assessed key clinical parameters during each RC. These included the child's feeding, weight, medications, color, breathing, oxygen saturation, and overall well-being. The clinical outcomes from this study are reported separately (Gillender et al, in press, December 2024).

Of the 26 parents who were interviewed 100% felt using videoconferencing for RCs was helpful, were pleased to have the opportunity to use it, and would recommend it to others. Benefits included reduced time and cost for the family in terms of travel, fuel, and childcare costs, having a planned call with a pediatric cardiology specialist at a time that worked for them and their family, and the flexibility of the RC.

Thematic analysis of the post-RC video call interviews using Braun and Clarke's approach [34] identified 5 key themes:

- The ease of using videoconferencing for RCs
- The reassurance of having regular RCs
- The value of the visual component of the RCs
- The opportunity to ask questions during RCs
- The non–health-related benefits of RCs

Discussion

Principal Findings

Parents caring for sick children are vulnerable to “social, psychological, physical, relational, individual, and financial” risks [35], which can lead to detrimental effects on the well-being of their children and other family members [36]. However, caring for children at home can have positive effects for the child, parents, and wider family, and strong, trusting relationships between parents and the clinical care team may reduce parental stress levels and contribute to resilience [37,38].

Remote patient monitoring has become more prevalent and relevant as the pressures on health care providers and service delivery increase. However, RC can only provide sustainable and optimal health care when considered within the reality of the patient lived experience; clinical expertise; and available finances, services, and resources.

In this project, over half of the parents had a baby whose CHD diagnosis was made postnatally. Navigating the complexities of new parenthood, an unexpected diagnosis, and new methods of interacting with health professionals using technology, all during the uncertainty of the COVID-19 pandemic, led to parents feeling frightened with deep concerns about all aspects of their child’s health.

> *I was frightened, it’s the only reason I said I would go home, if I had something like that [videoconferencing for RC], if they give me contact with somebody* [Mother 1027]

Parents’ Experiences of Videoconferencing Enabled Remote Consultations to Manage Their Child’s CHD

The Ease of Using Videoconferencing for Remote Consultations

Findings from the UTAUT questionnaire showed that using videoconferencing for RCs got easier over time and became more acceptable. Parents found the informal coaching in downloading and using the application to be very beneficial and the written instructions easy to follow. Although 27% (8/30) of parents reported limited experience of talking to others on video calls, they reported that they found the videoconferencing application easy to use, suggesting they would be more likely to connect.

> *You literally just click on the app, it’s…really straightforward, I called him [doctor] and it worked…it’s very simple* [Mother 1010]

Parents quickly became experienced using videoconferencing for RCs and meeting with the clinical team. They were better prepared for the calls, actively made decisions to improve the interactions, and set up in a way that worked best for them. For example, having their baby undressed for visual assessment, weighing their baby in advance, and having the oxygen saturation monitor nearby or attached to the baby. In addition, if there was an issue with the audio or video quality during a RC they reconnected to resolve the issues or used a forced stop of the videoconferencing application. As their skill and knowledge increased, their confidence increased, and they found it easier to ask questions.

> *Before I went on the calls I was a wee bit anxious…I didn't know what I was expecting, but it actually made me feel quite at ease because I know now that…every two weeks we do it* [Mother 1023]

The Reassurance of Having Regular Remote Consultations

Becoming a parent can have major physical, social, and psychological implications [39], and new parents require help and support from family and friends to successfully navigate their new role and responsibilities [40]. However, when their baby has a complex medical condition, support and guidance are also required from specialist medical teams, as well as building strong relationships to optimize the child’s care using the most appropriate techniques and technologies [35,41]. Remote monitoring, while essentially about the patient, also supports parents’ emotional well-being and empowers them which is essential for the continued and sustained welfare of their children.

> *I think it’s great to get the confidence to be able to take the lead in the child’s care and obviously have that support in the background. I think sometime parents can be overwhelmed by medical staff and they might think they’re not doing things right, but a parent’s intuition is always the best intuition I think* [Mother 1004]

The Value of the Visual Component of the Remote Consultations

This project aimed to provide the highest quality of interactions via synchronous RCs. Parents were impressed by the quality of the video and felt that the visual aspect was key for them. Theoretically, “ocularcentrism,” where people need to see each other to enable them to communicate more effectively, is likely an important determinant in their preference to use videoconferencing for RC [42].

> *Describing symptoms over the phone isn't that useful because they ask you what colour he is and it’s hard to describe a colour over the phone, it’s hard to describe his breathing over the phone, it’s so much better if they can just actually see him and look at him…the seeing bit is key* [Mother 1001]

RCs allow parents to care for their child at home while ensuring very sick children are rapidly admitted to a hospital when required [16]. The RBHSC team was experienced in carrying out RCs and in using the video and audio to assess babies and children, and parents trusted the doctor and the continuity of care.

> *I thought she [baby] just had reflux but it was [doctor] on the call made the call, calm as you like, “I'll see you in the Royal [RBHSC] in an hour”. And I was like, why is he dramatizing this?… Of course then when we arrived…that was that, she was going for a stent. But I didn't realise she was sick, because you know, to me she’s not blue, although she is blue*

> *to other people…. So I think, because I'm constantly looking at her, I didn't realise she was sick and I was blaming the machine [oxygen saturation monitor] and he was like "I think maybe you should just come on up," and I was thinking why's he taking me up that road?… and she was admitted…so without this [RC] I would never have ever in a million years ever phoned and said she's off form because for me it was reflux and I just thought she'll be fine…. When I got up there, I realised the extent of it, I totally owe her life to him…he was so calm, I just thought he was being dramatic, you know really checking her out…he saved her that day, he definitely did* [Mother 1003]

Opportunity to Ask Questions During Remote Consultations

In a web-based survey, 90% (n=10) of parents of children with CHD reported that the question *How many children have heart surgery and how many survive?* was important or really important to them [29]. Parents have many questions regarding their child's condition but often find it difficult to have the confidence or be "brave" enough to ask.

> *it gives me massive confidence, massive…as I say I wouldn't be panicky anyway but I've never had a cardiac baby before…. I do tend to have a lot of questions* [Mother 1024]

Non–Health-Related Benefits of Remote Consultations

Many parents simply cannot stay at the hospital with their sick child for long periods of time. They feel they neglect their other children, do not have time to travel long distances to the hospital, or do not have the finances or support infrastructure to do so, exacerbating their feelings of stress and anxiety. RC is convenient, as it reduces costs, time, childcare, travel, preparation, and waiting for children and their parents, especially for those in remote areas [15,19,43-46]. Parents in this project agreed with this.

> *it's just so convenient especially with home schooling at the minute because the three of them [other children] are at home…it saves me round trips so it therefore saves you on your pocket, it saves you time because it's not just an hour up the road and down the road, you have to consider your parking…then your appointment takes maybe three hours it's a whole day, a whole day, its mad!* [Mother 1003]

Flexibility of the timing of the RCs was important to parents to enable them to have some time to prepare for the call, and the overall convenience improved parents', and therefore their child's, experience. It also facilitated streamlined RCs and improved use of time for the clinicians.

> *It's so flexible which is brilliant it's not like having to be at the hospital for a certain time with parking and everything that goes with it…it would be half a day if we had to go to the hospital because getting packed up and all his stuff and medications, getting to the hospital, getting parked, getting in, and the phone call was 15, 20 minutes* [Mother 1019]

COVID-19

In response to the COVID-19 pandemic, the General Medical Council (GMC) [47] recommended that "doctors should...triage and treat patients by remote consultations where possible," and the Royal College of Physicians [48] stated "there has never been a time when effective remote consultations have been needed more." The number of visits and in-person consultations at the RBHSC were reduced during this project, therefore reducing the risk of infection for vulnerable children. Interestingly, however, COVID was only mentioned on 4 occasions by 4 parents. Further, 3 were not that concerned about COVID.

Additionally, 1 parent was concerned that their child could "catch something" while at the hospital. Nevertheless, they still wanted their child to have in-person consultations at the hospital.

> *if you're going up there [RBHSC] every week then obviously there's a chance…that something could happen or she could catch something…but I still like going up every so often just for that wee bit extra reassurance* [Mother 1013]

Comparison to Tandberg

The necessary move away from the Tandberg and Cisco remote monitoring system to the Pexip application RCs meant no installation of hardware was required. The application could be downloaded to any device, and RCs could begin immediately once children left the hospital allowing them to be discharged sooner. Compared to static Tandberg, the videoconferencing application was superior in terms of the cost of hardware installation and convenience, bed availability, carbon footprint, and potentially workforce sustainability. By using mobile phones, parents could zoom in on their baby, enabling the clinicians to visually assess the baby. The health care providers could also see the surroundings of the babies, which may be an important tool if there were concerns about the home environment. In 2018, the GMC [49] published a report commissioned to inform the regulatory requirements relating to telemedicine in the United Kingdom, with the key focus being to ensure that patients' safety was not compromised. The GMC [47] provided a flowchart to assist clinicians to "weigh up the factors" regarding whether to provide treatment remotely or in person. However, this guidance does not mention the technological tools and skills required of the patient or carer. The reported usefulness, usability, and acceptance of the videoconferencing application for RCs by parents suggest it would be rapidly adopted by parents who quickly and easily learn to use the application, set up to optimize the call, and troubleshoot, making it as easy as possible for them to connect and engage with clinicians.

Managing and monitoring the care of sick children are the main focus for clinical teams during RCs. However, they also have the potential to provide reassurance and support to parents by reducing their anxiety and giving them a vital role in the care and decisions regarding their own baby at a time when many may be overwhelmed by a CHD diagnosis. In a project in China, Zhang et al [50] used the WeChat platform for remote monitoring of infants with CHD. It included a clinician led live daily interactive question and answer session for parents and led to a reduction in parents' depression and anxiety [50].

Limitations

It is important to remember that while NI has the highest rates on fiber broadband availability in the United Kingdom, a proportion of the population have poor internet access, mainly homes in rural areas [51] both in NI and worldwide. However, no child should be disadvantaged by a lack of internet, and continued support, as required, from the RBHSC and in other jurisdictions in terms of hardware and software is warranted. Such provision should be viewed as an investment, not a cost. Worldwide, key to the success of RC provision is parent and carer involvement, including training, guidance, and support to enhance digital literacy and confidence in using technology.

Throughout the project, parents and the RBHSC pediatric cardiology team were clear that RCs should not and would not replace in-person consultations. Although they reported RCs were as good, parents still valued the hands-on, in-person consultations above RCs. Therefore, and as shown in this current project, a hybrid model of RCs and in-person consultations based on patient needs would provide the best possible care. However, the duration between in-person appointments may be lengthened if parents find this acceptable and children are well.

Caution is needed when using RCs for remote monitoring of children. Not all parents were regularly available for RCs, and it was suggested by 1 parent that some could use remote monitoring in negative ways by not disclosing details about the child's health if they faced financial or emotional difficulties.

> *In-person I know they'll not let me go home if she's not right whereas, if you were a wee bit careless you could mask what's going on…because you can't be bothered doing the [trip to the hospital] or the other thing is, probably if you struggled financially…maybe it's just not possible to do the trip so maybe you're going to tell lies* [Mother 1003]

As clinicians continue to use RCs more for remote monitoring, they are at risk of experiencing digital fatigue, "a state of mental exhaustion and disengagement caused due to prolonged exposure to digital tools, apps, and screens" [52]. Therefore, it is important to protect clinicians who are already under unprecedented levels of pressure as patient numbers continue to increase. It is also important that for clinicians who are new to RCs or are using a new software for RC, extra support and time are provided to develop their skills in identifying issues and using the technology.

Future Opportunities

As remote monitoring becomes more prevalent, future opportunities for additional functionality may include artificial intelligence (AI) and machine learning to enhance engagement and reduce workload. AI could be incorporated to schedule appointments, and natural language processing could be used to automatically parse and interpret RC dialog to provide personalized reminders and follow-up tasks. Machine learning algorithms could be embedded for continuous monitoring of and real-time feedback on data from oxygen saturation monitors, to identify high-risk patients and target interventions.

Acknowledgments

The research team would like to sincerely thank all of the children and their parents who took part in this study. Without the generosity of their time and expert lived experience, this project would not have been possible. This project was funded by Children's Heartbeat Trust and Ulster University.

Abstract

Background: Neonatal intensive care unit admissions of newborns are emotional and stressful for parents, influencing their mental and physical well-being and resulting in high rates of psychological morbidities. Significant research has been undertaken to understand and quantify the burden of a newborn's medical journey on parents' well-being. Simultaneously, an increase has been observed in the development and implementation of telemedicine interventions, defined as the remote delivery of health care. Telemedicine is used as an overarching term for different technological interventions grouped as real-time audio-visual communication, remote patient monitoring, and asynchronous communication. Various telemedicine interventions have been proposed and developed but scarcely with the primary goal of improving parental well-being during their newborn's medical journey.

Objective: This study aims to identify telemedicine interventions with the potential to improve parents' well-being and to present the methods used to measure their experience.

Methods: A scoping review was conducted, including empirical studies evaluating telemedicine in neonatal care that either measured parental well-being or included parents in the evaluation. Abstract and title screening, full-text screening, and data extraction were performed by three researchers. Two researchers were needed to reach decisions on both the inclusion and extraction of articles.

Results: The review included 50 out of 737 screened articles. Telemedicine interventions focused mainly on daily visits at the neonatal intensive care unit and discharge preparedness for parents. Surveys were the primary tool used for outcome measurement (36/50, 72%). Aspects of parents' well-being were evaluated in 62% (31/50) of studies. Telemedicine interventions developed to provide education and support showed a potential to improve self-efficacy and discharge preparedness and decrease anxiety and stress when they included a real-time telemedicine component.

Conclusions: This scoping review identified specific telemedicine interventions, such as real-time audio-visual communication and eHealth apps, that have the potential to improve parental well-being by enhancing self-efficacy and discharge preparedness, and reducing anxiety and stress. However, more insights are needed to understand how these interventions affect well-being. Parents should be included in future research in both the development and evaluation stages. It is important to not only measure parents' perceptions but also focus on the impact of a telemedicine intervention on their well-being.

KEYWORDS

telemedicine; telehealth; neonatal care; parental well-being; family-centered care; pediatrics; neonates; newborns; parents; neonatal intensive care unit; NICU

Introduction

Admission of a newborn to a neonatal intensive care unit (NICU) places a high emotional burden on parents [1]. This often unexpected neonatal admission exposes the parents to a high risk of developing psychological morbidities, including posttraumatic stress disorder [2]. Parental well-being, referring to the overall mental, emotional, and physical health of parents during and directly after the medical journey of their newborn, influences child development [3,4] and the risk of developing long-term psychological morbidities for the parents [5]. Their well-being is influenced by the stress or anxiety they experience due to the severity of the child's medical condition [6,7]. Additionally, their mechanisms for coping with the medical situation and traumatic moments, as well as their self-efficacy and confidence in their parenting skills, can further influence their well-being [7-9].

Despite the increasing awareness of the relevance of parents' well-being during the neonatal care journey, insights into parents' needs and effective interventions to enhance their well-being are lacking [10]. Steps have been taken to identify needs and factors that influence parental well-being [10-13]. Identified parental needs during the care journey include informational needs, emotional needs, involvement in decision-making, financial needs, practical needs, and ways to cope with transfers and discharge [10,11,14]. Furthermore, parent-infant bonding and social support are important factors associated with depressive symptoms within the first 12 months after discharge from the NICU [12,15]. Discharge from the hospital is affected by communication, unmet informational needs, and the management of expectations and perceptions, exposing an important role for peer support and improved communication by health care providers [13]. Consequently, suggested opportunities to improve parental well-being often focus on communication and informational provisions [16].

Telemedicine interventions are emerging, including within neonatal care [17]. Telemedicine is defined as the remote delivery of health care [18] and is often grouped in (1) remote patient monitoring, (2) real-time health care provider–to–health care provider or health care provider–to–patient consultations, and (3) asynchronous (non–real-time) telecommunication [19]. With telemedicine interventions focusing on the transfer of information, communication, and participation by family members, it has the potential to fulfill the exposed parental needs described above [20]. The importance of parental involvement when developing, evaluating, and implementing telemedicine interventions is underscored by the noticeable increase in the use of patient/parent-reported experience measures (PREMs) and patient/parent-reported outcome measures (PROMs) for evaluating telemedicine interventions [21]. Despite the potential and growing use of PREMs and PROMs, telemedicine interventions are rarely implemented with the primary aim of enhancing parental well-being [22,23]. Therefore, this study aimed to identify telemedicine interventions that potentially enhance parental well-being during the neonatal care journey by performing a scoping review.

Methods

The scoping review was conducted following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines for scoping reviews [24].

Eligibility Criteria

Using the PICO (Population, Intervention, Comparator, Outcome) framework, the following inclusion criteria were defined:

- The population/setting of the study must be during the neonatal care journey.
- The intervention must be a telemedicine intervention.
- There was no restriction on the comparator group.
- The outcome measures should include aspects of parental well-being or parents' perception of the intervention.
- The included studies must be published and use an empirical study design.

The neonatal care journey was demarcated from the neonate's admission to a neonatal ward in the first week of life and ranged from immediately after birth to 12 months of follow-up. Therefore, studies were excluded when they included only healthy neonates, neonates admitted to a nursery directly after birth, or neonates with congenital abnormalities admitted to a hospital ward later than the first week of life. Telemedicine was defined as the remote delivery of health care, without any restrictions on the technologies used [18]. Long existing technologies, such as telephonic consultations or SMS updates, were purposefully included in this review to include the whole variety of interventions. However, digital health applications that did not provide health care were excluded, such as electronic patient record systems, medical decision support tools, organization tools, or interventions used for training medical professionals. Eligible outcome measures including parental well-being or parents' perception of the intervention were (1) PREMs, for instance focusing on the usability or satisfaction of the intervention; (2) measures on how the intervention influences the parent's journey, for instance, travel time saved; and (3) PROMs regarding their well-being, such as depression, anxiety, self-efficacy, or posttraumatic stress disorder. These outcome measures were not confined to quantitative outcomes or validated questionnaires, as qualitative studies can provide a more nuanced description of experiences.

Articles published before the year 2000, not available in English or Dutch, without full-text availability, or with a nonempirical study design (protocols, reviews, editorials, etc) were excluded.

Search Strategy

Medline, Embase, Web of Science, Cochrane, and Google Scholar databases were searched using the following search terms: telemedicine, neonatal care, parents or caregivers, and experience or perspective (complete search is presented in Multimedia Appendix 1). The search was performed on February 23, 2024.

Screening

Title and abstracts were screened by three independent researchers (JW, CM, FB) using the Covidence (Veritas Health Innovation) program for systematic reviews. Two discussion sessions were organized to align the interpretation of the eligibility criteria. Two reviews were needed to reach a decision, and conflicts were resolved by discussion. Full-text screening was performed by JW, CM, and FB.

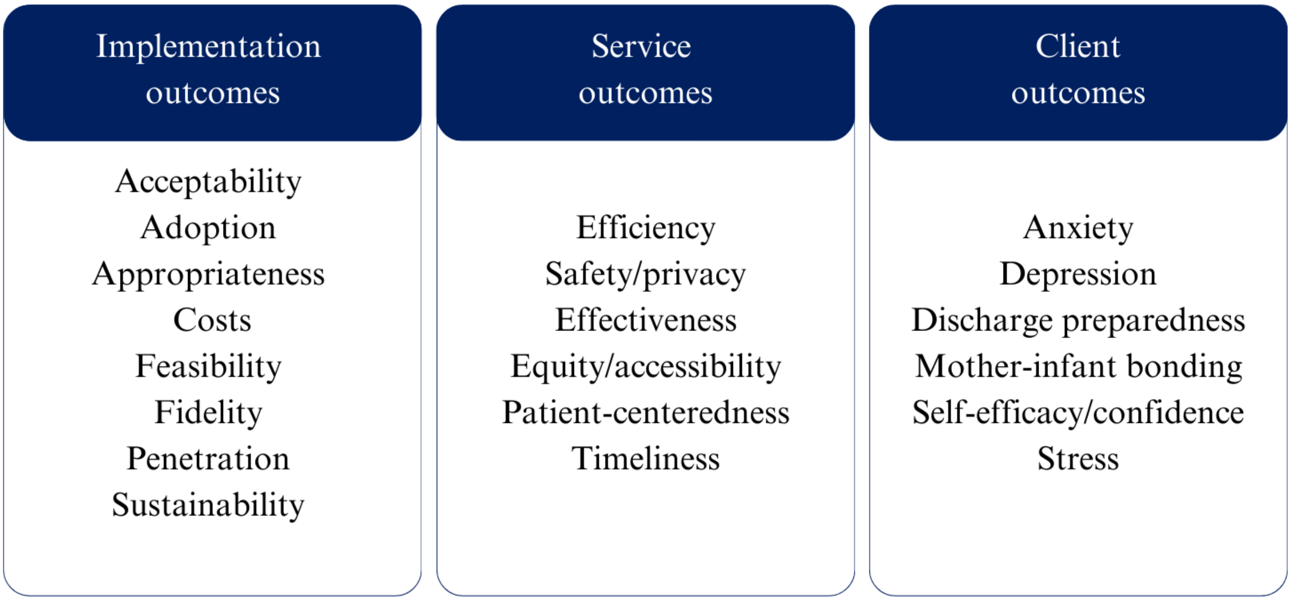
Data Extraction

The data extraction form was reviewed and tested by three reviewers (CM, FB, JW). Data were extracted by CW, and JW verified all extraction data. The following data items were extracted per included study:

- Background information on the study: title, author, year of publication, country of origin, study design, and aim of the study
- Information on the telemedicine intervention: name of the intervention, purpose, type of telemedicine; users, and the moment of use within the neonatal care journey
- Methods of evaluation and the participants
- Outcomes of the study

Outcomes were extracted following the implementation science framework by Proctor et al [25] suggesting the categorization of outcomes into implementation outcomes (how is the implementation used and appreciated in clinical practice?), service outcomes (how does the implementation influence the way clinical care is delivered?), and health outcomes (how does the implementation affect patient/parent outcomes?). Relevant outcomes for this specific scoping review are visualized in Figure 1. For health outcomes, this review focused on components of parental well-being, for instance, stress levels, confidence in their parenting role, and self-efficacy. This outcome framework categorizes PREMs into implementation or service outcomes and PROMs into health outcomes [21].

Figure 1. Outcome categorization used for this scoping review adapted from the framework of Proctor et al [25].



Data Synthesis

Baseline characteristics of the included studies were presented for the study design, type of telemedicine, methods, and results categories. Extracted data were presented in an overview table and synthesized qualitatively for each step in the neonatal care journey. We defined the following steps in the journey: daily visits at the NICU, ongoing support at the NICU, transfers between NICUs, discharge from the hospital to home, and the first 12 months of follow-up.

Ethics and Involvement

Due to the literature review nature of this study, ethical approval was deemed unnecessary. Parents and patients were involved in the design of the study, the interpretation of the results, and writing of the manuscript via experts from the neonatal parent and patient advocacy organization Care4Neo (author SOB).

Results

Characteristics of Included Studies

After removing duplicates, 737 studies were selected for title and abstract screening. Interrater agreements were 78.9%, 82%, and 82.6% with a Cohen κ of 0.42, 0.59, and 0.48, respectively. Full texts were screened for 158 articles, resulting in the selection of 50 included studies (see flowchart in Figure 2). Complete data extraction of the included studies is presented in Multimedia Appendix 2. Included articles were predominantly published recently, with 76% (n=38) published in the last 5 years, and 50% (n=25) originated in the United States, with Scandinavian countries as the runner-up (n=10, 20%). Parents were included when designing the intervention in 12% (6/50) of studies. Frequently mentioned purposes of the telemedicine intervention were to remotely follow up on the neonate after discharge and save the family travel time (n=14, 28%) and to allow parents to see their infant at the NICU (n=11, 22%). All purposes are presented in Table 1.

Within the 50 articles, surveys (n=36, 72%) and interviews (n=10, 20%) were the most used evaluation methods, and they included 6 to 298 caregivers per study. Most of the interventions included real-time telemedicine technology (n=32, 64%) with 58% (29/50) including videoconferencing. Mobile apps facilitated the intervention in 21 studies, mainly used for educational or supporting content (8/21, 38%) and the transition to home and remote follow-up (15/21, 71%). Interventions were often part of a comprehensive health care program, using multiple technologies to facilitate different moments of contact between parents and health care providers (Multimedia Appendix 2).

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) inclusion flowchart.

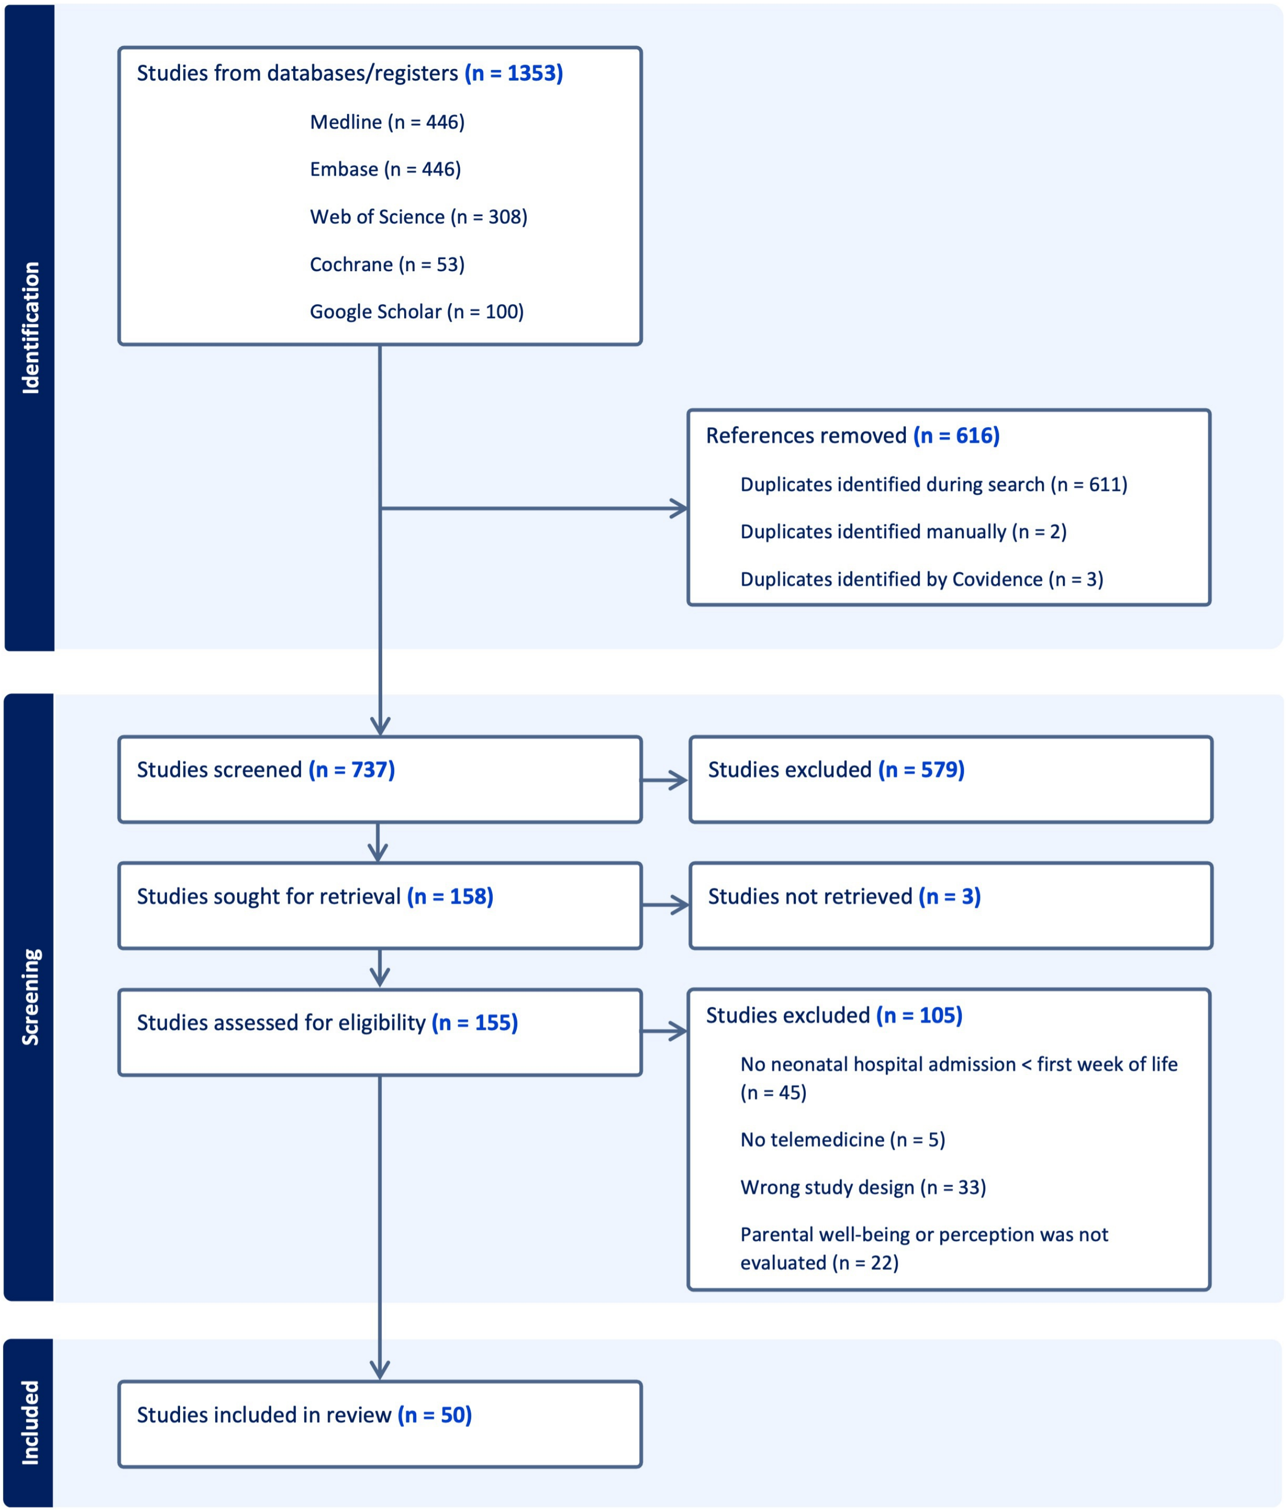


Table . Purpose of the telemedicine interventions.

Purpose of telemedicine intervention	Frequency (n=50), n (%)
Remote follow-up and save the family travel time	14 (28)
Allow parents to see their infant in the NICU[a]	11 (22)
Improve transition from NICU to home	8 (16)
Provide psychosocial and emotional support	6 (12)
Provide education to enhance confidence and self-efficacy	5 (10)
Facilitate telerounds with a remote expert to prevent transfers	3 (6)
Provide regular medical updates to families	3 (6)

[a] NICU: neonatal intensive care unit.

Outcome Measurements

The assessed outcome categories and methods of outcome measurement are presented in Table 2. Three out of 50 studies were in the design phase and were only able to hypothesize the outcomes, and therefore they were not included in the analysis of the outcome measures. The majority of studies used surveys (36/47, 77%) to assess the parents' satisfaction and the effect on their well-being. Qualitative research methods such as interviews, focus groups, and workshops were applied in 23% (11/47) of studies and in all (3/3) studies designing an intervention. Of the 4 studies that used health records or usage logs, 2 studies presented usage logs in addition to qualitative data, whereas 2 studies only used data from the medical records system for establishing outcomes (Multimedia Appendix 2).

The surveys used to evaluate implementation outcomes varied. Some were validated questionnaires like the telemedicine usability questionnaire. Almost all used a 5-point Likert scale format. Service outcomes were either qualitative themes (eg, privacy concerns, accessibility of health care) or the potentially avoided travel distance or time. The Parental Stressor Scale (PSS-NICU) was the most frequently used standardized questionnaire (8/25, 32%) evaluating parental stress. The Parenting Sense of Competence Scale was used in 16% (4/25) of studies to evaluate self-efficacy. Nine of the 25 studies that evaluated client outcomes using surveys used a nonvalidated questionnaire, developed by the research team, to evaluate parental discharge preparedness, self-efficacy, or satisfaction with the delivered health care. An overview of the used questionnaires is shown in Multimedia Appendix 3. Client outcomes assessing the impact on the parents' well-being were focused on depression, anxiety, stress, bonding, and self-efficacy.

Table . The number of studies assessing different outcome categories and the methods used.

Methods used	Implementation outcomes (n=33)[a], n (%)	Service outcomes (n=11)[a], n (%)	Client outcomes (n=31)[a], n (%)
Surveys	26 (79)	8 (73)	25 (81)
Qualitative methods	9 (27)	3 (27)	7 (23)
Health records/usage logs	2 (6)	1 (9)	1 (3)

[a] Only 47 of the 50 articles were examined because the remaining 3 studies were in the design phase and were therefore only able to hypothesize the outcomes.

Parental-Neonatal Care Journey

Overview of the Journey

An overview of telemedicine interventions for each moment in the parental-neonatal care journey is presented in Figure 3. Their impact on implementation outcomes, service outcomes, and health outcomes is presented in Table 3. Most telemedicine interventions focused on the follow-up after hospital discharge (22/50, 44%), the discharge from the NICU to home (18/50, 36%), or daily visits to the NICU (18/50, 36%). None of the interventions focused on transfers between hospital wards or hospitals.

Figure 3. Overview of included telemedicine interventions for each step in the neonatal care journey. NICU: neonatal intensive care unit.

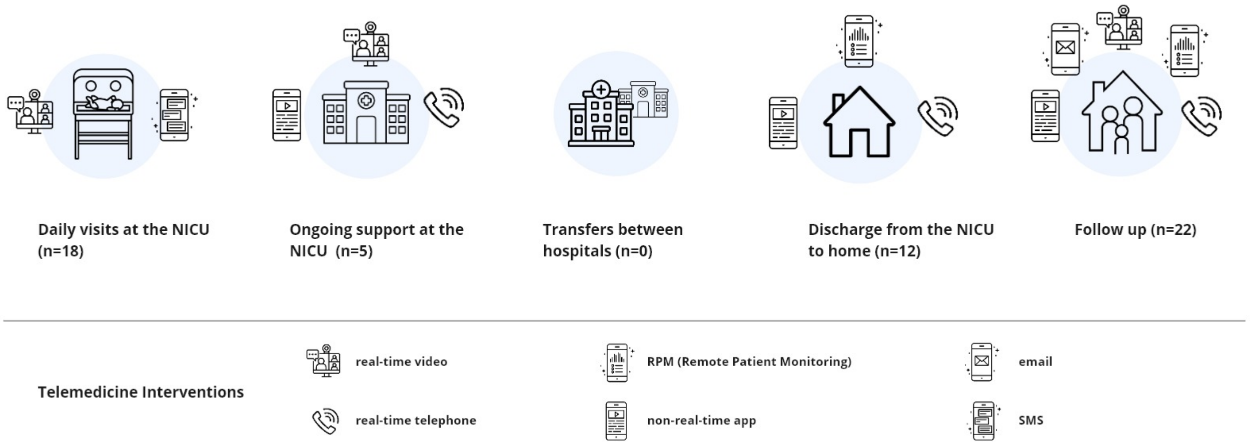

Table . Telemedicine interventions per moment in the parental-neonatal care journey.

Moment in the journey, purpose, and technology	Implementation outcomes	Service outcomes	Client outcomes
Daily visits at the NICU[a] (n=18)			
Allow parents to see their infant remotely [26-36]			
Real-time video	• *Acceptability*: high satisfaction • *Adoption*: high usage rates • *Appropriateness*: easy to use • *Feasibility*: training of staff is necessary, technical issues • *Sustainability*: how to schedule maintenance of the tool	• Privacy concerns	• Decreased stress (2 survey studies; PSS-NICU[b]) • No difference in stress, anxiety, depression (2 survey studies; STAI-S[c]. PSS-NICU, MIB[d], DASS-21[e]) • Reduction of stress, anxiety and increase in confidence (3 interview studies) • Increased stress due to video unavailability or traumatic images without explanation. • Hypervigilance due to 24-7 video availability (interview study)
Telerounds with remote expert [37-39]			
Real-time video	• *Acceptability*: high satisfaction. Comfortable talking to remote neonatologist • *Feasibility*: high video/audio quality	• Higher attendance of parents to daily rounds	• Not evaluated[f]
Virtual family-centered rounds [36,40]			
Real-time video	• *Acceptability*: high satisfaction • *Adoption*: 50% used intervention • *Appropriateness*: easy to use	• Higher attendance of parents to daily rounds	• NICU staff felt they had a positive impact on caregivers
Provide medical updates [41,42]			
Real-time video, SMS	• Videoconferencing was *feasible*, *acceptable* and *reliable*	• No impact on satisfaction with treatment and staff	• No reduction in parental concerns (interview study)
Provide lactation support [43]			
Real-time video	• Not evaluated	• Not evaluated	• Increased percentage exclusively breastfeeding

[o] MABISC: Mother and Baby Interaction Scale.

Daily Visits to the NICU

All telemedicine interventions at the NICU used real-time audiovisual communication, either to allow parents to see their infants or for daily rounds with remote parents or experts. Facilitating a bedside camera accessible for parents resulted in high usage rates. It also resulted in a decrease in stress and anxiety, and an increase in confidence in multiple survey studies with randomized controlled designs [26,27] and interview studies [28-30]. Other studies found nonsignificant differences for stress, anxiety, and bonding with evident positive trends in open-ended questions [31,32].

Three important negative outcomes were found: technical aspects, privacy, and hypervigilance. Incidence of technical issues ranged widely (from 5% to 60%) and staff reported doubts about training and maintenance protocols [27,28,31,41]. Furthermore, unexpected unavailability of the video connection triggered stress and fear in parents, not knowing what was happening to their infant [28,33]. Privacy concerns for both the infant and the NICU staff were mentioned [28,33]. Extensive security evaluation of the data connection prior to implementation was included in most study protocols to ensure privacy for the infant. Privacy of the NICU staff, on the other hand, was an unexpected negative outcome in two studies [27,33]. Their main concerns were the fear of behaving differently when being watched by parents while taking care of the infant and the liability risk for neonatologists when medical emergencies are being recorded. Lastly, the possibility of watching your infant 24-7 resulted in hypervigilance for some parents [28]. Parents explained that being able to constantly watch their infant made their home feel less restful. Virtual family-centered rounds, some with remote experts present, all had high satisfaction rates. Rosenthal et al [40] showed a relatively low adoption rate, with only 48.6% of parents attending the virtual rounds at least once. However, there was an evident increase in parental participation during rounds in this group, with the attendance rate being 3.4 times higher compared to the control group without virtual rounds, suggesting a positive effect in a selected group of parents. Makkar et al [37] also found higher participation rates in the telerounds with remote experts. Impact on parental health outcomes was not evaluated for virtual rounds.

Ongoing Support and Education

Although interventions for educational and supportive purposes targeted different moments in the neonatal care journey, they shared the same telemedicine aspects. These interventions were designed as comprehensive programs including a smartphone- or tablet-based application with interactive functions and planned moments of contact with health care professionals.

An example is the “My Bridgham Baby” app [44], including (1) practical information regarding the NICU; (2) information on the role as a parent for their admitted infant; (3) support services for parents and their families; (4) discharge education, checklists and milestones before discharge; (5) mental health services for parents; (6) advice on financial and insurance resources; and (7) information regarding the follow-up. This app also includes a chat function to ask questions to the medical team. Self-efficacy [48,59] and discharge preparedness increased [44,49], and one controlled trial showed nonsignificant trends in parenting confidence [50]. Two studies included parental perspectives in the design phase by hosting focus groups, both recommending the integration of social support facilitation into the app [45,54]. Interventions that included real-time telemedicine (telephone or video) showed a decrease in anxiety and stress [46,47,53].

Discharge Preparedness and Follow-Up

Almost half of the included studies focused on the transition to home and follow-up (24/50, 48%). The majority of these interventions (16/24, 67%) used a combination of telemedicine modalities: apps and videoconferences. Only a few of them (3/24, 13%) used the app as a means to actively gather information on the patient [57,61,66], the definition of remote patient monitoring. As expected, studies concluded that telemedicine results in accessible health care, saving travel time and money for parents [51,55,56,58,68,72]. Furthermore, the parental sense of competence at home increased, probably due to the easily accessible option of asking questions to professionals [52,55,58,61,63,65,66,71,72].

Discussion

Principal Findings

In this scoping review, we aimed to identify the potential of telemedicine interventions to improve parental well-being during the neonatal care journey of their infant. Telemedicine interventions included in our review had two main purposes: (1) to overcome physical distance through remote follow-ups and virtual family-centered rounds with remote experts, allowing parents to see their infant remotely, and (2) to prepare parents for discharge by providing information and social support. The majority of the interventions were part of a comprehensive program, entailing a telemedicine intervention with, for instance, a structured set-up over time, multiple functionalities, and moments of contact with health care providers. Of the included studies, 70% (33/47) evaluated parental opinions on the intervention, like usability and technical quality, and 66% (31/47) assessed the actual impact of the intervention on the parents’ well-being, like stress, self-efficacy, depression symptoms, and unmet needs. This review draws attention to three main gaps in the literature:

- None of the telemedicine interventions focused on the transfers between hospitals, despite this being an urgent unmet need for parents [11].
- There is a need for assessing not only implementation satisfaction but also the actual impact on the parents’ well-being, ideally in both the short- and long-term.
- The variety of methods and questionnaires used to evaluate parents’ well-being and experiences creates a great challenge to compare the outcomes of different studies, which is a commonly mentioned issue when integrating results of parents’ well-being evaluations at the NICU [9]. Also, the variety of methods for evaluating telemedicine interventions aligns with a recent systematic review examining the evaluation of patient and staff experience with remote patient monitoring, which similarly noted a lack of consensus and standardization in evaluation methods [73].

Categorization of telemedicine interventions was challenging. Included interventions were often part of a comprehensive program including multiple technologies. Unfortunately, a significant number of included studies failed to fully describe the program and, perhaps more importantly, to present the results behind parents’ satisfaction with the intervention. Moreover, the majority of the underlying studies provided limited information on the characteristics of the included parents. Factors such as age, socioeconomic status, family situation, and ethnicity influence parental needs [74,75] and are relevant when interpreting the observed impact of telemedicine, individualizing interventions, and ensuring availability of technology to all patients. Integrating findings from the included studies on both intervention satisfaction and its impact on parents’ well-being was therefore challenging. To enhance generalizability and implementation, it is recommended to provide comprehensive descriptions of the entire program and the included participants, and to particularly highlight intervention components that are vital for parents.

Furthermore, the impact on parental well-being is mainly established in studies using technology as a means to provide emotional or educational support. This suggests using the technology should not be the primary goal, but that the potential impact derived from the actual content of the delivered care, education, or support should be the goal. In other words, the telemedicine intervention should be the means and not the end. On the other hand, usage and uptake of the telemedicine intervention are essential in order to reach the intended impact. It remains important to reflect on the parental needs that are being targeted by the intervention and if telemedicine is the best intervention to improve the experience. More comprehensive, probably qualitative, research into the parental journey and the unmet needs is advised before designing new interventions. Subsequently, it is essential to invite parents to participate when designing and implementing a telemedicine intervention, using a participatory study design with, for instance, co-creation sessions.

Strengths and Limitations

By purposefully including the whole range of technological interventions, including mature technologies like telephone consultations, SMS, or email services which have been part of health care for decades [76], we aimed to create a comprehensive overview. Furthermore, by including studies that evaluate not only the impact on parental well-being but also parental perceptions of telemedicine interventions, we were able to demonstrate the current level of parental involvement in the different phases of telemedicine research, including designing, implementing, and evaluating interventions. Also, we did not limit our inclusion to specific study designs. These three considerations resulted in a complete overview of all technological interventions that have been studied. Despite the scoping nature of the review, and therefore missing the quality appraisal, the three reviewers facilitated a robust and transparent inclusion process by predefining eligibility criteria, performing validation sessions, and extracting data with two independent researchers.

Despite efforts to be comprehensive, this review likely missed some studies. More specifically, by excluding protocols and trial registrations, we overlooked ongoing studies, such as a cluster randomized controlled trial for virtual family-centered hospital rounds [77] and the neoPARTNER study [78]. Considering the majority of included studies were published within the last 5 years, we expect the number of studies currently being performed to be relevant. Another challenge in this review was to capture the entire scope of the parental journey, as a lack of universal terminology and definitions posed significant obstacles. To minimize the risk of missing important parental aspects, we chose very broad terms for the search string (experience, perspective, perception, depression, anxiety, stress, satisfaction, etc). With this extensive search string, we screened and included articles focusing also on parents’ views of the technology instead of solely reviewing the impact on their care journey.

Practical Implications

Based on the included studies, several practical recommendations can be provided. This review clearly found educational and supportive telemedicine interventions, often delivered through a mobile or tablet application with multiple functionalities, have a positive impact on discharge preparedness. Furthermore, bedside cameras can be useful to improve infant bonding and reduce stress when caregivers are unable to be present at the NICU. However, an important remark is that privacy concerns of medical personnel, hypervigilance, and increased stress are pitfalls of the continuous availability of a bedside camera. Remote follow-up was often provided by a telemedicine program that includes an app and scheduled contact moments with health care providers (video or telephone). While remote follow-up improves the accessibility of health care by saving parents travel time and making parental confidence increase, it has not been proven to reduce stress, depression, or anxiety. The opportunities of telemedicine interventions, as described above, prove to be effective when used in the context of a comprehensive telemedicine program including informational provisions, moments of communication, and social support.

Conclusion

Telemedicine interventions have the opportunity to improve parents’ well-being during their neonatal care journey, especially when enhancing discharge preparedness and when aiming to overcome physical distance using bedside webcams, virtual family-centered rounds, or remote follow-ups. We advise future researchers to (1) properly describe their telemedicine intervention to enhance generalizability and (2) assess the impact on parents’ well-being when evaluating the intervention, ideally using a combination of validated questionnaires (PROMs; eg, the Parental Stressor Scale) and in-depth interviews. Furthermore, when designing and piloting new interventions, a critical reflection on the targeted parental needs, by involving parents in the study and using co-creation sessions, is essential to improve their journey.

Acknowledgments

This research is supported by Convergence | Healthy Start, a program of the Convergence Alliance—Delft University of Technology, Erasmus University Rotterdam, and Erasmus Medical Center—to improve the future of new generations. Furthermore, the authors wish to thank Maarten Engel from the Erasmus MC Medical Library for developing and updating the search strategies.

Authors' Contributions

JW and FB, together with MK, SOB, and HRT designed the study. JW, FB, and CM were responsible for article screening and data extraction. FB and CM made visualizations. HRT, SOB, IR, and MK contributed to interpreting the results. JW wrote the manuscript, with FB and HRT as co-writers. All authors reviewed the manuscript and agreed with the final version.

Abstract

Background: Since the COVID-19 pandemic, telemedicine has been widely integrated into primary care pediatrics. While initial studies showed some concern for disparities in telemedicine use, telemedicine uptake for pediatric patients in a low-income, primarily Latino community over a sustained period has yet to be described.

Objective: We aimed to assess the relationship between demographics, patient portal activation, and telemedicine visits, as well as characterize diagnoses addressed in telemedicine, in a low-income, primarily Latino population over time.

Methods: A multidisciplinary team conducted outreach for telemedicine and patient portal activation with the adoption of a new electronic health record. Data were collected on all in-person and telemedicine visits from February 2020 through April 2021 for 4 community-based pediatric practices. The outcomes included patient portal activation, telemedicine use, and reason for telemedicine visits. Bivariate tests and multivariate regression analyses were conducted to assess the independent effects of demographics on the likelihood of portal activation and having a telemedicine visit. Telemedicine diagnoses were categorized, and subanalyses were conducted to explore variations by age and month.

Results: There were 12,377 unique patients and 7127 telemedicine visits. Latino patients made up 83.4% (n=8959) of the population. Nearly all patients (n=10,830, 87.5%) had an activated portal, and 33.8% (n=4169) had at least 1 telemedicine visit. Portal activation decreased with age >2 years (2-4 years: adjusted odds ratio [aOR] 0.62, 95% CI 0.51-0.76; 5-11 years: aOR 0.28, 95% CI 0.23-0.32; 12-14 years: aOR 0.29, 95% CI 0.23-0.35; and 15-17 years: aOR 0.46, 95% CI 0.36-0.58). Spanish-speaking (aOR 0.52, 95% CI 0.45-0.59) and non-Latino patients (aOR 0.64, 95% CI 0.54-0.76) had decreased odds of activation and having a telemedicine visit (aOR 0.81, 95% CI 0.74-0.89 and aOR 0.71, 95% CI 0.62-0.81, respectively). The top 5 diagnostic categories for telemedicine were infectious disease (n=1749, 26.1%), dermatology (n=1287, 19.5%), gastrointestinal (n=771, 11.7%), well and follow-up care (n=459, 7%), and other specialty-related care (n=415, 6.3%). Infectious disease showed the most variation over time. Age-based patterns included a decrease in the proportion of infectious disease diagnoses by increasing age group and a higher proportion of well and follow-up care in older ages. Additional telemedicine diagnoses included common infant concerns for patients younger than 2 years of age; pulmonary, asthma, and allergy concerns for toddler or school-age children; behavioral health concerns for younger adolescents; and genitourinary and gynecologic concerns for older adolescents.

Conclusions: The high engagement across demographics suggests feasibility and interest in telemedicine in this low-income, primarily Latino population, which may be attributable to the strength of outreach. Language-based disparities were still present. Telemedicine was used for a wide range of diagnoses. As telemedicine remains a vital component of pediatric health care, targeted interventions may enhance engagement to serve diverse pediatric patient populations.

Introduction

Before the COVID-19 pandemic, telemedicine was described as having the capacity to revolutionize pediatric care provision [1]. Despite this promise, only 15% of pediatricians reported using telemedicine in 2016 [2]. The most cited barriers then included insufficient payment, a lack of confidence in diagnoses that were made through telemedicine, patient reluctance and perceived lack of usefulness, and insufficient infrastructure [2,3]. The COVID-19 public health emergency triggered a rapid national shift to telemedicine, and decreased regulations and better payment parity allowed its adoption. As telemedicine has expanded, concerns about its potential to exacerbate health disparities have been raised [4-6]. The limited data that exist show that low digital health literacy, cultural preferences, and limited access to the internet and technological devices may limit engagement in telemedicine visits for certain populations [7]. Given the wide adoption of telemedicine, it is important to understand patterns of telemedicine uptake and use in diverse communities. In this study, we aim to characterize telemedicine visits for over a year during the pandemic in a low-income, primarily Latino population.

Methods

Study Environment

This study evaluated the patterns of outpatient telemedicine use among families of patients younger than 18 years of age from 4 community-based pediatric practices affiliated with NewYork-Presbyterian Hospital/Columbia University Irving Medical Center (NYP/CUIMC), New York. These practices are part of an ambulatory care network staffed by a single pediatric group practice using a common electronic health record (EHR) and have around 19,000 patients. The practices serve a primarily Latino and publicly insured population and provide primary care and refer out for subspecialty care. Demographic and visit data were collected for all patients with in-person or telemedicine visits during the study period. The study period spanned from February 2020 when a new EHR system was launched (described in the Telemedicine Implementation section), and data collection extended through April 2021.

Telemedicine Implementation

In February 2020, a new EHR, Epic Systems, was launched across NYP/CUIMC. When the COVID-19 pandemic began in March 2020, NYP/CUIMC rapidly expanded telemedicine capacity across the network. Pediatric telemedicine was still in the pilot phase before the pandemic, orchestrated by 1 clinical champion. Early in the pandemic, there was an expansion of staff outreach. Extensive bilingual phone outreach for patient portal activation began in March 2020. Teams prioritized rapid patient enrollment due to the ongoing pandemic. Telemedicine capabilities were quickly expanded to accommodate acute care concerns and follow-up needs. Telemedicine visits were conducted through an Epic Systems video app. Patients were required to have access to a smartphone, tablet, or computer with internet capacity. If using a mobile device, they needed to download and install the Epic MyChart app, and then register for an account, which can be done in English or Spanish.

Although patients had the option to self-enroll digitally there was significant outreach to assist patients with the enrollment process. In March 2020, teams were created for the express purpose of patient enrollment. The bilingual team (Spanish or English) consisted of 17 staff and was interpreter supported for other languages. Administrators pulled data from the prior EHR and created detailed spreadsheets of all patients for enrollment. Staff was trained in enrollment, including health care proxy setup, as well as data management to track enrollment. There were rapid cycle performance improvement meetings to optimize protocols. Staff called patients and parents and assisted them in enrolling portal accounts. In some cases, families were assisted to create email accounts, as this was required for account access. A subset of patients with high risk was additionally prioritized by the primary care sites for outreach. Patients were deemed high risk by the criteria of the federal Maternal and Child Health Bureau’s children with special health care needs designation [8]. Many high-risk patients had a community health worker or care manager on their care team, and these staff also assisted in setting up the portal account. In some cases, community health workers used video calls to aid in setting up portal access. Additionally, if patients did not already have a portal account at the time of an in-person visit, providers or staff at the clinic could assist with portal access in person. When outreach was completed over the phone to set up portal access, the staff member confirmed portal setup by asking if the patients received an automated welcome message or if they could see their appointments or other portal components after setup. In our EHR, each patient chart clearly indicates whether they have activated their portal, and this is also confirmed by staff and providers at patient appointments.

Most telemedicine appointments were initiated when parents requested an appointment for an acute concern. The nursing staff triaged the concern and determined whether to schedule an in-person or telemedicine visit. Triaging protocols were agreed upon in advance by nursing and physician representatives and evolved throughout the COVID-19 pandemic. For patients with a primary language other than English, team members used a third - party interpreter service.

Study Variables and Outcomes

Patient demographics including age, sex, race, ethnicity, preferred language, and insurance status were extracted from the EHR for all individual patients who were seen in person or on telemedicine. All ages reported refer to the patient's age. Race and ethnicity data were collected by self-report.

Our institution has been part of a multi-institutional framework to more accurately collect race and ethnicity data in service of identifying and addressing health disparities, which has now been adapted by many other large health systems across the country since 2020 [9,10]. We collect information from patients using the standard US Office of Management and Budget 2-question format for race and ethnicity as well as 2 follow-up questions specified by the New York State Department of Health regarding granular ethnicity and granular race. Race and ethnicity values are typically captured during registration, either by front desk staff or on a tablet used by patients to electronically register at appointments. Patients were informed that it is optional to self-report and that patient information is confidential.

Data were collected for all patient visits within the study period, including both in-person and telemedicine visits. The primary study outcomes were patient portal activation (needed for telemedicine visits) and the presence of a video visit, referred to herein as a telemedicine visit. Another variable characterized was the primary diagnosis from telemedicine visits.

For diagnosis data, categories were created by the research team (MSS, PRP, and EB-S) after a review of the primary diagnosis of visits in our initial data in a qualitative manner. Two team members (MSS and EB-S) reviewed and classified all diagnoses manually into categories. A third team member (PRP) then reviewed all of the diagnosis classifications, grouped categories together with iterative feedback from authors, and clarified any ambiguous diagnoses. Each visit diagnosis as coded in the EHR was only assigned to 1 particular category. When there was ambiguity regarding categorization, the full-visit documentation was reviewed to most accurately categorize the diagnosis, and each of these decisions was reviewed by 2 authors (PRP and EB-S). The categorization was iterative with continuous refinement and validation until a consensus was reached.

Statistical Analysis

Analyses on demographic data and the presence of portal activation reflect the dataset of individual patients (n=12,377). Descriptive outcomes of diagnoses seen on telemedicine reflect unique telemedicine visits (n=7127), in which patients who have had multiple telemedicine visits are represented more than once. Chi-square analyses were conducted to examine associations between patient demographics and portal activation and having a telemedicine visit (separately). Multivariable logistical regression analyses were then conducted. Any variable that had a significant univariate 2-tailed *t* test at $P \leq .10$ was used as a variable for the multivariable analysis, based on the literature on purposeful selection [11,12]. For portal activation, covariates included were age (categorical: <2, 2-4, 4-11, and 12-18 years), language (categorical: Spanish, English, and other), and ethnicity (Latino and non-Latino). For the presence of a telemedicine visit, covariates included were age (categorical: <2, 2-4, 4-11, and 12-18 years), language (categorical: Spanish, English, and other), ethnicity (Latino and non-Latino), and race (White, Black, and other). There were no additional covariates in the model.

On the telemedicine visit data (n=7127), diagnoses from telemedicine visits were categorized and described overall. Subanalyses were conducted to explore variations in diagnoses by age and month. Statistical analyses were performed using SPSS software (version 28; IBM Corp). The significance level was set at $\alpha=.05$.

Ethical Considerations

The study protocol was reviewed and approved by the Columbia University Irving Medical Center Institutional Review Board (#AAAS8260). This institutional review board approval covered secondary analysis without additional consent. Data collection, storage, analysis, and reporting adhered to institutional guidelines. There was no compensation of participants, as only secondary data were used.

Results

Overall, there were 12,377 unique patients with visits during the time period. Half (n=6183, 50%) of the patients were female, 52.6% (n=6509) were younger than 5 years of age, 44.6% (n=5497) were Spanish speaking, 83.4% (n=8959) were Latino, and 21% (n=2160) were Black (Table 1). Insurance data from televisits showed that 95% (n=6360/6695) of patients were publicly insured. Of all patients (N=12,377), 10,830 (87.5%) had activated the patient portal. Of all patients, 33.8% (n=4169) had at least 1 telemedicine visit. Of those who activated their portal account and subsequently had an in-person or video visit, 38.5% (n=4169/10830) had a video visit. Of those with a telemedicine visit, 37.7% (n=1572/4169) had more than 1 telemedicine visit, the median number of visits was 1 (IQR 1-2; range 1-15).

The highest proportion of patient portal activation was for patients at the 2 extremes of age ranges. Of all patients younger than 2 years of age (n=4390), 94.1% (n=4129) had activated the portal, and of those between 15 and 17 years of age (n=1090), 87.2% (n=950) had portal activation. School-age children (5-11 years; n=3503) had the lowest rate at 80.1% (n=2807). On multivariable logistic regression analysis, decreased odds of portal activation were seen with age >2 years (2-4 years: adjusted odds ratio [aOR] 0.62, 95% CI 0.51-0.76; 5-11 years: aOR 0.28, 95% CI 0.23-0.32; 12-14 years: aOR 0.29, 95% CI 0.23-0.35; and 15-17 years: aOR 0.46, 95% CI 0.36-0.58). Decreased odds of portal access were seen for those speaking Spanish (aOR 0.28, 95% CI 0.23-0.32) or another non-English non-Spanish language (aOR 0.62, 95% CI 0.47-0.81) and being non-Latino (aOR 0.64, 95% CI 0.54-0.76; Table 1). Demographic characteristics associated with having had at least 1 telemedicine visit were similar but not the same as those for portal activation. School-age children were again least likely to have had at least 1 visit compared to those younger than 2 years of age (aOR 0.80, 95% CI 0.72-0.90), but adolescents had slightly greater odds of having a visit (aOR 1.17, 95% CI 1.00-1.36). Decreased odds of a visit were seen for those who spoke Spanish (aOR 0.81, 95% CI 0.74-0.89) or other non-English and non-Spanish language (aOR 0.65, 95% CI 0.52-0.81) or were non-Latino (aOR 0.71, 95% CI 0.62-0.81). Those who did not identify as Black or White also had decreased odds of having a telemedicine visit (aOR 0.89, 95% CI 0.81-0.98; Table 1).

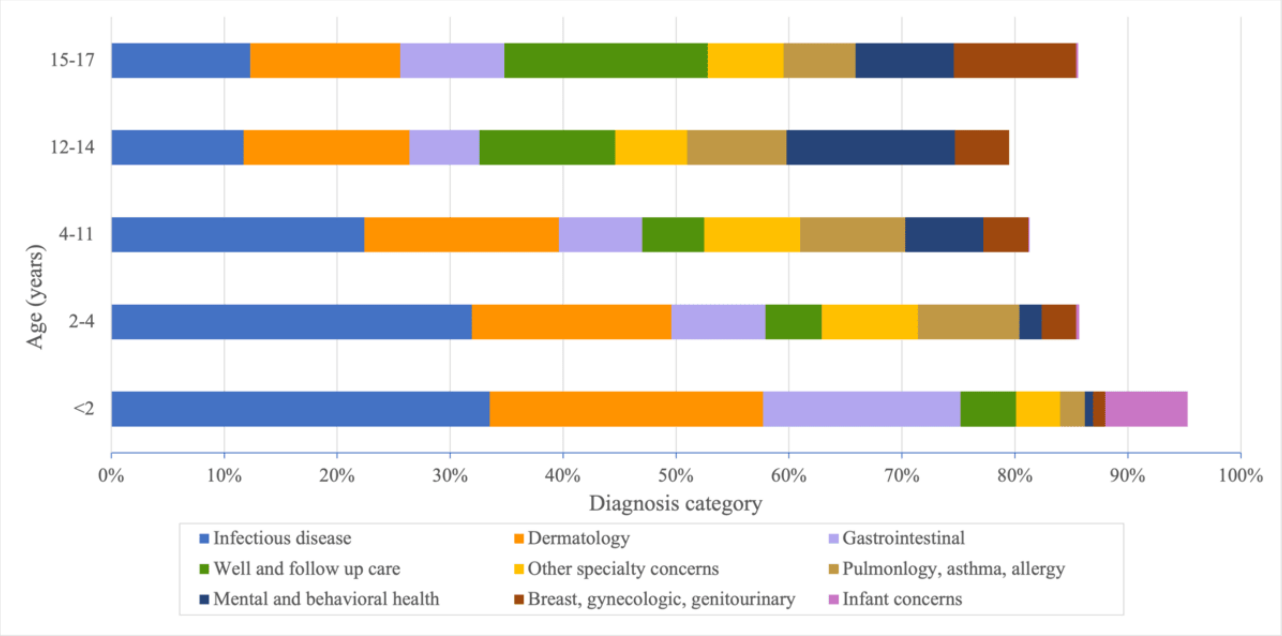
[f] Not applicable.

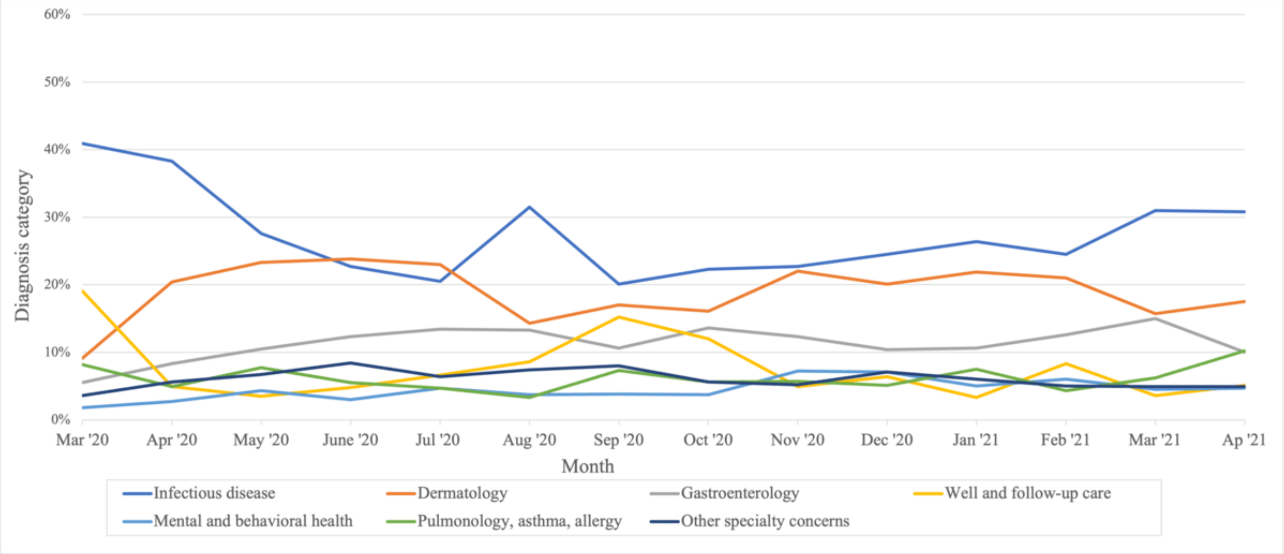
During the study period, there were 7127 telemedicine visits. The top 5 diagnoses categories were infectious (n=1860, 26.1%), dermatology (n=1389, 19.5%), gastrointestinal (n=771, 11.7%), well and follow-up care (n=499, 7%), and other specialty-related care (n=449, 6.3%). Patterns in telemedicine diagnoses differed by age (Figure 1). Infectious disease, the most common overall diagnosis category, was high in all age groups. However, there was a steady decrease in the proportion of the infectious disease category by increasing age group. For example, in visits for children of 0-2 years of age (n=2663), infectious disease made up 33.5% (n=892) of all visits versus only 12.3% (75/610) of visits for adolescents of 15-17 years of age. Dermatologic concerns were the second-most predominant diagnosis category for all age groups. There were also age-based patterns in well and follow-up care, as well care was more predominant for older age groups. For the 0- to 2-year age group (n=4390), there was a high proportion of gastrointestinal concerns (n=467, 17.5%) as well as other infant concerns (n=195, 7.3%), which included breastfeeding problems, colic, nasolacrimal duct stenosis, and teething. In the 2- to 4-year age group (and 5- to 11-year age group), pulmonary, asthma, and allergy-related diagnoses were the third-most prevalent concern. In the 12- to 14-year age group, the most predominant category was behavioral and mental health concerns (n=93). For the 15- to 17-year age group, genitourinary, gynecologic, and breast concerns were within the top 5 categories (n=66), which was not seen for any other age group.

Figure 1. Age-based variation in telemedicine diagnosis categories.



Patterns in diagnoses also changed by month (Figure 2). The number of video visits overall rose in spring 2020, peaking in May 2020 (n=629) and then decreasing in June (n=609), July (n=536), and August (n=520). After a small bump in September (n=558), telemedicine visits made up between 400 and 530 visits per month. At the onset of telemedicine visits in March 2020, the infectious disease made up the highest proportion of visits (45/110, 40.9%), and well and follow-up care accounted for an additional 19.1% (21/110). The proportion of infectious disease cases declined in the spring, then rose again to peak by August 2020, and after this, consistently made up the highest proportion of telemedicine diagnoses. In our clinic system, as in-person visits became more available later in the pandemic, infectious disease diagnoses continued to make up the highest proportion of telemedicine visits. After the initial high proportion of well and follow-up care visits, these visits declined rapidly in April 2020, then rose again to a peak in August and September 2020. In the spring of 2020, the proportion of dermatology diagnoses as a fraction of all diagnoses rose steadily until June 2020 when dermatology diagnoses made up of 23.8% (145/608 visits in June) of televisits. After this, dermatologic diagnoses made up between one-tenth and one-quarter of all cases. Other diagnosis categories showed less variation over time. After a slow increase over the spring of 2020, gastrointestinal diagnoses made up the third-most common category for most months. Mental and behavioral health made up a very small proportion of cases initially (2/110, 1.8%) but slowly rose up to 7.2% (33/461) by December 2020, after which it made up between 4.7% and 7.1% (from 23/491 to 32/453) of cases.

Figure 2. Temporal variation in telemedicine diagnosis categories.



Discussion

Principal Findings

In this study, which assessed telemedicine use immediately after rollout in the early pandemic period, we found that widespread access to telemedicine, as measured by portal activation, is possible in a low-income, primarily Latino community. In this population, telemedicine appointments were used for a wide array of diagnoses across the age spectrum. Our findings have implications for the use of telemedicine to support and augment pediatric primary care provision for diverse patient populations.

Comparison to Prior Work

In our study population, which was largely publicly insured, we found that of all patients seen, 87.5% (10,830/12,377) had an active portal account, and a third had at least 1 telemedicine visit with the use of multipronged bilingual outreach for portal activation. Schenker et al [13] studied a pediatric primary care practice during the first 5 months of the pandemic and found that public insurance was a significant negative predictor of having had a video visit. We did identify some demographic disparities, particularly in language. Non-English speakers had decreased odds of portal activation and of having a video visit, with the lowest visits among those who spoke neither English nor Spanish. Similar to our findings, Blundell et al [14] found that in a pediatric dermatology practice, patients speaking Spanish had lower rates of having an email address in the EHR and lower rates of having an activated patient portal account. Conversely, Schenker et al [13] did not find language to be a significant predictor of telemedicine use. Rodriguez et al [15] found that patients with limited English proficiency had less access to telemedicine and also reported worse experiences with video visits as compared to in-person visits. The authors posit that this may be related to difficulty with interpreter use, providers or patients perceiving video visits to be less effective, or digital barriers. It is likely that these barriers are also present in our patient population [15]. While our clinical sites are fully bilingual and have a strict interpreter policy with access to all languages, outreach in different languages to let families know about multilingual telehealth could be helpful both in person at visits by front desk staff and providers and by nurses when providing triage. Paper sheets that have portal access codes and set-up instructions could be made available in multiple languages (not only English or Spanish) for staff to distribute. Other interventions in the literature include the use of patient navigators for telemedicine [16]. The use of telemedicine navigators was found to benefit physicians and patients along with being cost-effective. Some authors have also described digital rooming [17]. This involves the use of medical assistants to call patients prior to telemedicine appointments for help with connecting to the visit digitally and found some success with increasing the likelihood of patients appropriately connecting to the visit. This is not specifically targeted at non-English and non-Spanish speakers; however, if adapted to serve these populations, for example, with the routine use of interpreters, it could also function to increase accessibility. In our literature review, we find that both interventions have been used to a greater extent for adult populations [16,17].

Interestingly, in our study population, being Latino was associated with higher odds of both portal activation and having at least 1 visit. It is important to note that we consider our race and ethnicity data to reflect social constructs, and differences in outcomes by race and ethnicity provide an understanding of structural health care disparities that may further drive inequities [18]. Understanding differences in telemedicine use by race and ethnicity provides evidence for targeted interventions to decrease institutional or systemic bias and racism. Looking across the pediatric and adult literature, the relationship of telemedicine use by race and ethnicity has been mixed. Several studies have described that White patients are more likely to use telemedicine [13,19]. Some studies early in the pandemic show decreased telemedicine use in Latino or Hispanic populations compared to White patients [20,21]. However, others such as Samson et al [22] found that Hispanic and Asian patients had higher use of telemedicine than White or Black patients. Some authors have hypothesized that there are modifying factors, such as geographical differences, or community preferences that affect use within ethnic groups [23].

Strengths and Limitations

It is not entirely clear why our Latino patient use was higher than non-Latino use. We believe that the differences seen in our study are at least partially attributable to our outreach. Our team aimed to increase access for all patients and also focused on decreasing barriers for Latino and Spanish-speaking patients. A multidisciplinary approach to enrollment was critical—for example, staff, patient financial advisors, care managers, community health workers, and care providers could all assist with enrollment and interact with patients in different contexts. Our enrollment occurred with major tenets of cultural competency in place, described as the "tailoring of health care delivery to meet patients' social, cultural and linguistic needs" [24]. Many staff on the enrollment team, particularly staff, patient financial advisors, and community health workers, come from the same community and regional background as our patients. Many of them identify as Latino and spoke Spanish. Anecdotally, staff reported that when they were able to identify with families, they could provide more trust and reassurance for families who had reservations about the process of enrollment or telemedicine participation. Further, as part of the drive for patient enrollment, staff were supported to iterate enrollment protocols, particularly to target barriers for families with respect to language, culture, and health literacy such as using language for enrollment that was patient-responsive and reflective of the local Spanish dialect. We believe that devoting time and resources to patient enrollment and engaging patient-facing staff to increase our cultural competency are reflected in our results of Latino enrollment.

In regard to the use of video visits, there may be other systematic differences between non-Latino and Latino populations that make telemedicine visits more convenient or accessible for Latino patients in our study population as compared to in-person visits. These could be social determinants of health, such as job or transportation-related factors, or even demographic factors such as parent age or parental comfort with technology used for video visits. Our high level of engagement across demographics, including in Latino patients, suggests feasibility and interest in telemedicine in this low-income, diverse population and underscores the importance of outreach.

Telemedicine engagement, as indicated both by portal activation and telemedicine visits, also showed age-related variation. Patients younger than 2 years of age and those between 15 and 17 years showed the most engagement. Other authors have reported similar patterns. Walters et al [19] reported families of patients younger the 1 year of age as more likely to use telemedicine, whereas Schenker et al [13] found that older patients were more likely to have had video visits. The frequency of well-child visits for infants and a higher rate of contact with the health care system may have influenced higher portal activation rates for children younger than 2 years of age. In our health care system, adolescents are given individual portals with enhanced confidentiality at 12 years of age. Older teens in the 15- to 17-year age group likely have the skills to independently access their portal and obtain telemedicine and may find televisits a convenient way to access care. Research on adolescents and caregivers has shown that telemedicine is widely acceptable for this age group [25,26]. Of all age groups, school age children (5-11 years) had the lowest proportion of telemedicine use. Possible barriers may be that parents of elementary school children have a stronger preference for in-person visits or the times telehealth visits are offered are not amenable to parent or child schedules as compared to younger and older age groups.

We found that video visits were used for a wide range of diagnoses including acute care, well care, and mental health concerns. Video visit diagnosis patterns can be assumed to be guided by the needs of patients and families, as well as the triage protocols used by nursing staff who directed patients to in-person or video visits. Temporal variation in diagnoses illustrates the evolving nature of the COVID-19 pandemic, with a high prevalence of infectious disease case concerns in March 2020 and subsequent intermittent peaks. Well and follow-up care also peaked in the spring of 2020 when in-person care was reserved for more acute concerns but subsequently did not remain as common a reason for telemedicine. Overall, the categories of infectious disease, gastroenterology, and dermatology stayed high throughout the study period, showing that telemedicine may be a useful modality to address these common pediatric complaints. The persistence of the infectious disease category highlights the relevance of telemedicine to manage routine infectious conditions beyond COVID-19. In a qualitative study on telemedicine for acute respiratory concerns, parents reported that they prefer telemedicine because it is easier and it decreases wait time, disruptions in schedules, and exposure to other ill children in a waiting room [27]. Telemedicine may also help with use patterns elsewhere in a health care system. For example, Walters et al [19] asked caregivers who used telemedicine for acute concerns about potential alternatives and found that a substantial portion would have gone to the emergency department or urgent care center (16.5%) or opted not to seek care (11.3%) if telemedicine was not an option. Indeed, our most common categories—infectious disease, dermatologic, and gastrointestinal concerns—make a large component of pediatric urgent care and emergency department visits [28]. Our findings have potential implications for strengthening telemedicine policies, for example, improving triage algorithms for common diagnostic categories, so that telehealth visits provided by the medical home can serve as an effective alternative to using emergency services or meet the needs of patients who have barriers to in-person visits.

There were also notable patterns in diagnosis categories by age group. Though common in all age groups, infectious disease visits were less common for older individuals. Infectious disease was the most common diagnosis category for infants through school-aged children, but for younger adolescents, mental health was most predominant, and for older adolescents, it was well and follow-up care. Dermatologic concerns consistently ranked as the second-most predominant category for all groups. Additional associations by age included common infant concerns for patients younger than 2 years of age; pulmonary, asthma, and allergy-related concerns for school-age children; and genitourinary and gynecologic concerns for older adolescents. These age-dependent shifts in diagnoses emphasize the evolving health care needs of pediatric patients and the acceptability by both parents and providers to address a variety of concerns through telemedicine. Other studies have found age differences in telemedicine use [13,29] but have not examined age-related variation in diagnoses to the extent of this study. In the postpandemic era, both primary care pediatricians and caregivers expect to use telemedicine as a routine part of care provision for acute as well as chronic concerns [19,30-32]. As telemedicine further integrates into primary care practices, understanding age-based variation in use can help strengthen practice-level policies to appropriately and optimally meet the evolving needs of patients and caregivers.

This study has several limitations. First, our findings have geographical and temporal limitations for generalizability. Given that we studied telemedicine use with the onset of the pandemic from February 2020 to April 2021, we do not have a prepandemic comparison group. Our data here also reflect the unique time period in the first year of the pandemic when there was a relative lack of familiarity with web-based medicine. We know telehealth use has evolved during and beyond the pandemic. For example, Solo-Josephson et al [33] found that later in the pandemic, patients using telemedicine had a larger range of preferred languages spoken. The unique manner in which the COVID-19 pandemic progressed in New York City and the local health care and public policy responses are not necessarily representative of other geographical locations. Furthermore, given our community, our findings may be more generalizable to other populations with a predominant proportion of Latino patients or another similar ethnic majority. Other studies have described a similar pivot to telemedicine in pediatric care with the onset of the pandemic [13,14,27,30-32,34,35]. As compared to other institutions, the deployment of the Epic Systems EHR was a unique circumstance at the beginning of our project. Though portal activation was not required of all patients, there was a great deal of outreach to promote activation during the initial few months. The fact that we were able to capture activation in real time was significant, and our results indicate the importance of outreach with such new interventions. However, it is possible that telemedicine use would be different if there had not been a temporal overlap with the deployment of a new EHR. In addition, in our study, the outcomes measured were patient portal activation and the presence of a telemedicine visit. While these are important metrics, we do not describe other factors related to use, such as the reasons for choosing telemedicine over in-person visits, barriers to telemedicine, and patient satisfaction with telemedicine. Further, there were some limitations related to data categorization. Regarding demographic data, we recognize that EHRs have historically had inaccuracies in race and ethnicity data, particularly for Latino, Asian, Native American, and Pacific Islander patients [36]. As it relates to pediatric patients, EHRs and databases may also show discordance for children versus adults, given the additional challenges of gathering data for pediatric patients [10]. Our institution has been part of a multi-institutional framework, starting in 2020, to address some of these challenges. This campaign, We Ask Because We Care, is an exemplar of improvement in data collection. This methodology has now been adapted by other large health systems in the United States since 2020 [9,10]. The framework includes continuous measurement and monitoring with real-time dashboards. Finally, there were also some challenges related to the classification of the diagnosis data. In the diagnosis data, there were some diagnoses that could arguably fit into multiple categories (eg, chest pain as “cardiac” or “musculoskeletal”). We aimed to enhance validity and limit misclassification through detailed chart review where there was ambiguity, as well as iterative categorization and verification by multiple authors.

Future Directions

Avenues for future research include longer-term analysis and qualitative exploration of barriers and facilitators of telemedicine in specific populations, including Latino and Spanish-speaking families, such as factors related to demographic or socioeconomic conditions. Another avenue of further study would be to investigate variations in preferences or satisfaction with telemedicine in different age groups, particularly in the postpandemic period.

Conclusions

Our study provides valuable insights into the implementation of telemedicine in pediatric primary care, particularly for Latino patients, as well as use for common pediatric diagnoses across age groups and over time. As telemedicine has emerged as a vital component of pediatric health care, these findings can inform targeted interventions to enhance accessibility, improve engagement, and tailor telemedicine services to the diverse needs of pediatric patients and families.

Abstract

Background: There is a lack of studies examining the long-term outcomes of web-based parent training programs implemented in clinical settings during the COVID-19 pandemic.

Objective: The aim is to study 2-year outcomes of families with 3- to 8-year-old children referred from family counseling centers to the Finnish Strongest Families Smart Website (SFSW), which provides digital parent training with telephone coaching aimed at treating child disruptive behaviors.

Methods: Counseling centers in Helsinki identified fifty 3- to 8-year-old children with high levels of disruptive behavioral problems. Child psychopathology and functioning as well as parenting styles and parental mental health were collected from parents at baseline; posttreatment; and at 6-, 12-, and 24-month follow-ups.

Results: The SFSW program had positive long-term changes in child psychopathology and parenting skills. Improvements in child psychopathology, including Strengths and Difficulties Questionnaire total score (Cohen *d*=0.47; *P*<.001), Strengths and Difficulties Questionnaire conduct scores (Cohen *d*=0.65; *P*<.001), and Affective Reactivity Index irritability scores (Cohen *d*=0.52; *P*<.001), were maintained until the 24-month follow-up. Similarly, changes in parenting skills measured with the Parenting Scale, including overreactivity (Cohen *d*=0.41; *P*=.001) and laxness (Cohen *d*=0.26; *P*=.02), were maintained until the 24-month follow-up. However, parental hostility changes were not maintained at long-term follow-up (Cohen *d*=−0.04; *P*=.70).

Conclusions: The study shows that the SFSW parent training program can yield significant long-term benefits. Findings indicate that the benefits of the treatment may vary between different parenting styles, which is important to consider when developing more personalized parenting interventions.

Introduction

There is growing evidence from randomized controlled trials (RCTs) that parents can be trained to intervene and reduce child disruptive behaviors and improve their parenting skills [1-3]. Parent training has been found to be the most effective way to prevent and treat disruptive behaviors (patterns of, eg, defiant, disobedient, hostile, and externalizing behavior) among children [4-6] and is considered one of the most-validated therapeutic techniques in child mental health [7]. In the face of the unmet need for accessible evidence-based treatment programs to tackle early-onset childhood disruptive behaviors, digitally administered remote treatments provide solutions that require fewer personnel, that may be less stigmatizing, and that can reach geographically remote areas [8,9]. Examining the long-term outcomes of an intervention is an essential step in ensuring the sustainability of its effects. A recent meta-analysis on RCTs showed that parenting interventions based on social learning theory are effective in reducing physical and emotional violence at immediate posttest, but effects decrease over time [10]. However, to our knowledge, there are no long-term follow-ups (ie, more than 12 months) of digital parent training interventions in clinical settings. The Finnish Strongest Families Smart Website (SFSW) intervention is an 11-week program that includes parent training delivered through a digital platform and assisted by weekly telephone coaching. Previously, we conducted an RCT, screening families at regular health checkups for 4-year-old children. Children who had parent-reported high levels of disruptive behavior were screened for targeted SFSW intervention. The sample included 232 children in each study group, an intervention group, and an educational control group. At a 24-month follow-up after randomization, the results maintained efficacy in reducing a wide range of child psychopathology and improving parenting skills [11].

Child behavior problems are associated with psychological distress and financial costs and with a poor long-term outlook if they are not addressed [1]. Early intervention is crucial to help mitigate these impacts and support healthier development trajectories. This study targets an important gap in the current literature on long-term follow-ups of digital parent training interventions in clinical settings. We assessed the long-term outcomes of families participating in the SFSW parent training program in a clinical setting at baseline and at 12 and 24 months after baseline. A unique contribution of this study is that the SFSW parent training program was administered to the study cohort during the worst phase of the COVID-19 pandemic when the Helsinki capital region was partially isolated from other parts of Finland. Other services were severely limited, albeit the need for services was great. The SFSW program was an already existing, empirically tested, and, importantly, digitalized intervention targeting children's disruptive behavior problems. Due to the crisis, it was considered ethically inappropriate to conduct a randomized controlled study design in this study. The program completion rate was high. The 6-month follow-up findings of this program were very promising and have been reported previously [12]. There were significant changes in most of the child psychopathology measures, including the Child Behavior Checklist (CBCL) externalizing score (mean 7.0, 95% CI 4.9 - 9.0; *P*<.001), and when parenting skills were measured with the Parenting Scale (PS), the results showed significant changes in the total score (mean 0.5, 95% CI 0.4 - 0.7; *P*<.001) [12].

Our aim with this paper is to report long-term changes in children's functioning, psychopathology levels, parenting skills, and well-being from baseline until the 24-month follow-up. We hypothesized that the previously reported positive effects of the SFSW at the 6-month follow-up [12] would be at least partly maintained at the 24-month follow-up.

Methods

Study Population

The study included families with children between the ages of 3 and 8 years who exhibited elevated levels of disruptive behavior when screened by professionals from 8 different family counseling centers in Helsinki. Family counseling centers operate under social services and provide low-threshold services. The centers contribute to child development by reinforcing parenting skills and family relationships. They provide direct support, offer advice to assisting services, and facilitate referrals to specialized services. At family counseling centers, parent training that addresses child-rearing challenges is offered through individual or group sessions. The recruitment was based on identified needs. Health care and social welfare professionals from the counseling centers identified families that were in need of support for child disruptive behavior and selected families who were suitable for the remotely administered SFSW parent training program. During the pandemic lockdowns, face-to-face sessions were not possible, underscoring the importance of remote support methods.

Ethical Considerations

Ethics approval for the study was received from the ethics committee of the University of Turku (statement 25/2018), and the study also received a research permit from the city of Helsinki (HEL 2020-006651). Parents provided written informed consent and were advised that participation in the study was voluntary and they had the right to withdraw at any time. This is a single-group study design with repeated measurements. Parents completed questionnaires at baseline; posttreatment; and at 6, 12, and 24 months after starting the program. The study encompassed 50 families and took place from May 2020 to November 2022. Earlier findings comparing baseline, posttreatment, and 6-month follow-up results have been reported previously [12].

Recruitment, Eligibility, and Procedure

The professionals identified children with high levels of disruptive behavior problems. In addition, parents completed the Strengths and Difficulties Questionnaire (SDQ) [13,14] and were included if their child had a high level of conduct problems (≥5 points in the SDQ conduct scale) and if the parents perceived their child to have difficulties concerning emotions, behavior, or social interactions based on one item inquiring parents about these aspects. Additionally, inclusion in the study required at least 1 parent to be a native Finnish or Swedish speaker with access to both a telephone and a device with internet connectivity. Exclusion criteria were if a child had been diagnosed with autism, Down syndrome, fetal alcohol syndrome, an intellectual disability, or severe mental disorders, which would indicate a need for services beyond the scope of the digital SFSW program. Eligible families were invited to participate and directed to the SFSW website to provide their formal consent and fill in the baseline questionnaires. Commencing with the completion of baseline questionnaires, participants progressed through SFSW. A flowchart on the study procedures is provided in inMultimedia Appendix 1.

Intervention

The SFSW parent training program used digital materials (eg, psychoeducational material, video clips, and home exercises) and telephone coaching. The program focused on enhancing skills to improve parent-child relationships, complemented by weekly telephone sessions conducted by trained family coaches—licensed health care professionals, including nurses and public health nurses. The content of each web-based session included an introduction, session content, video exercises, troubleshooting, review, and practical application of the new skills. Each session featured multimedia components and digital exercises, and parents were encouraged to complete the session before the next phone call. All coaching calls were systematically recorded and subjected to random audits by the coach supervisor to ensure fidelity. The telephone sessions were scheduled at the end of the previous weekly call for a duration of 1 hour each. The family coach followed up in case the family missed an appointment, and possible rescheduling of coaching sessions was done per SMS text message or email contact by the parent.

The SFSW program has previously been shown to be effective [11,15] and can successfully make the transition to implementation settings [12,16,17]. Table 1 includes an outline of the weekly themes covered in SFSW. The program was sequential, that is, the parents completed 1-week theme before moving to the next. The primary goal was for parents to recognize positive behaviors in their children and respond positively. The second aim was to apply learned skills in everyday situations, using positive methods to reinforce the child's positive behavior. The end of the program focused on solidifying the application of newfound positive parenting skills in daily life to support the child's positive behavior. Parents practiced these skills with their children and discussed their progress during weekly telephone calls with their family coach, which were scheduled aiming to ensure sustainability beyond the program's completion. As previously reported [12], the average time spent on the program website for each of the 11 themes was 48.0 (SD 25.6) minutes, and the mean duration of telephone coaching was 35.3 (SD 8.8) minutes per call. The total mean duration per theme, including both digital materials and telephone coaching, was 83.3 (SD 28.0) minutes.

Table . Themes of the SFSW[a] web-based parent training program for children with behavioral problems.

Session	Goals
1. Notice the good	Boost the child's self-esteem, boost the parent's self-esteem, and change the parent's view of their child
2. Spread attention around	Strengthen the child's empathy skills
3. Ignore whining and complaining	Teach parents self-regulation
4. Prepare for changes	Reinforce good daily routines
5. Plan ahead at home	Boost the self-esteem of the child and parent and involve the child in planning
6. Chart and stickers	Involve the child in planning and reinforce good daily routines
7. Plan ahead outside the home	Boost the self-esteem of the child and parent and involve the child in planning
8. Working with daycare	Help the child to manage and succeed
9. Time-out	Teach self-regulation and consistency
10 and 11. Problem-solving revision and future application of skills	Teach parents skills to support child development and prepare for future challenges
12. Booster	Remind parents of positive proactive parenting skills

[a] SFSW: Strongest Families Smart Website.

Measurements

The parents completed questionnaires at baseline, after the program, and at 6, 12, and 24 months after they had started the program. In addition, demographic details of the family, children, and parents were collected during the screening phase. All of the measurements used in this study have demonstrated adequate reliability and criterion validity metrics and were described more extensively in our previous paper [12]. For brevity, we mention them briefly below, while a comprehensive description is provided in Multimedia Appendix 2.

Child Psychopathology and Functioning

Child psychopathology was assessed using the Finnish version of the 25-item SDQ [13,14], which measures challenges the child experiences in emotions, behavior, or social interactions [18]. Perceived difficulties were gauged through a single question regarding challenges in emotions, behavior, or social interactions, with response options ranging from no difficulties to severe difficulties. Disruptive behavior was gauged by the externalizing subscale of the CBCL for ages 1.5 - 5 years (99 items) [19], focusing on an externalizing subscale with 24 items related to attention issues and aggressive behavior (our primary outcome) along with the CBCL's total score. Child irritability was measured by the Affective Reactivity Index (ARI), which includes 6 irritability symptom items and 1 impairment item [20]. A 17-item questionnaire, derived from Barkley's Home Situations Questionnaire [21], measured the parents' experiences of their child's functioning and behavior in daily situations. We used the 24-item Inventory of Callous-Unemotional Traits (ICU) [22] to assess 3 precursors of child psychopathy: callousness, uncaring, and unemotional traits [23,24].

Parenting, Parental Mental Health, and Satisfaction

The PS, a 30-item tool, was used to evaluate 3 dysfunctional parenting discipline styles: laxness, overreactivity, and hostility, reflecting rule enforcement, responses to mistakes, and using verbal or physical force, respectively [25,26]. We used the 21-item Depression, Anxiety, and Stress Scale (DASS-21) to assess parental stress, anxiety, and depression symptoms in the past week [27].

Statistical Analysis

Descriptive statistics include numbers and percentages for categorical variables and means and SDs for continuous variables. The categorical variables were analyzed with Pearson chi-square or Fisher exact tests and the continuous variables with 2-sample 2-tailed *t* test. We analyzed the outcome variables using linear mixed-effect models for repeated measurements with time as a within-factor. The modeling framework enables to use restricted maximum estimation method, which handles data with missing observations. Therefore, there was no need to apply any separate imputation method. We used linear contrasts to estimate changes from baseline to 12 and 24 months as well as changes from 12 to 24 months. We included the sex, age, and maternal education of the children as covariates in all models. The McNemar test was applied to test the change in the number of children with a total SDQ score above the 90th percentile (ie, abnormal range) at baseline and at the 24-month follow-up. The effect sizes of all outcome variables were calculated as 2-tailed *t* test effect sizes using Cohen *d*. The statistical analyses were performed using SAS statistical software (version 9.4; SAS Institute Inc).

Results

Participant Characteristics

The study comprised 50 families who were referred to the program, of which 44 (88%) completed the whole 11-week SFSW program. In total, 24-month follow-up assessments were obtained from 37 (74%) families. As shown in Table 2, 37 (74%) of the 50 children were boys. A total of 48 (96%) children had definitive or severe behavioral problems at baseline, and only 2 (4%) had minor behavioral problems based on a single item in the parent report, “Overall, do you think that your child has difficulties in 1 or more of the following areas: emotions, behavior, or being able to get on with other people?” Table 2 also presents a comparison between the families who completed the 24-month follow-up and those who did not. The table shows the difference in maternal education—in the noncompleter group, mothers were less educated. The completers and noncompleters did not differ on parenting style measures or psychopathology symptoms.

Table . Baseline characteristics of enrolled families, and comparison between families completing and those not completing the 24-month follow-up measurements.

Long-Term Changes in Child and Parenting Measures

Descriptive statistics of child psychopathology, child function level, parental skills, and parental mental health at baseline and at 12 and 24 months after baseline are presented in Table 3. A statistical comparison of the different time points is presented in Table 4. In terms of child psychopathology, significant improvements between baseline and the 12-month follow-up as well as between baseline and the 24-month follow-up were found in CBCL total scores and externalizing scores, SDQ total scores and most subscales (emotional, conduct, hyperactivity, and peer problems), and irritability measured with the ARI scale. At the same time, there was a significant deterioration in CBCL total and externalizing scores and SDQ prosocial behavior scores between the 12-month and 24-month follow-ups.

Table . Child psychopathology, child functioning level, parental skills, and parental mental health at baseline and 12 months and 24 months after the baseline (n=50).

We conducted an additional analysis of 37 (74%) of the 50 parents who completed the SDQ questionnaire both at baseline and at the 24-month follow-up as well as the parent training program. This analysis showed that 30 (81%) of the 37 children had a total SDQ score above the 90th percentile (ie, abnormal range) at baseline, while only 14 (38%) remained in the abnormal range at the 24-month follow-up (*P*<.001, McNemar test), based on the population sample of 4‐ to 16-year-old children [12]. To examine the children in the proximity of cutoff thresholds, we also used the 80th percentile cutoff point (ie, abnormal or border range), which showed that 36 (97%) children were above the cutoff point at baseline, while the respective figure at the 24-month follow-up was 23 (62%), indicating a highly significant change (*P*<.001, McNemar test).

When parents were asked about perceived difficulties regarding their child’s behavior problems with a single question—“Overall, do you think that your child has difficulties in 1 or more of the following areas: emotions, behavior, or being able to get on with other people?”—at baseline, 2 (5%) of 37 had no or minor problems, 20 (54%) had definite problems, and 15 (41%) had severe problems. The respective figures at the 24-month follow-up were 14 (38%), 14 (38%), and 9 (24%; *P*=.001, McNemar-Bowker test).

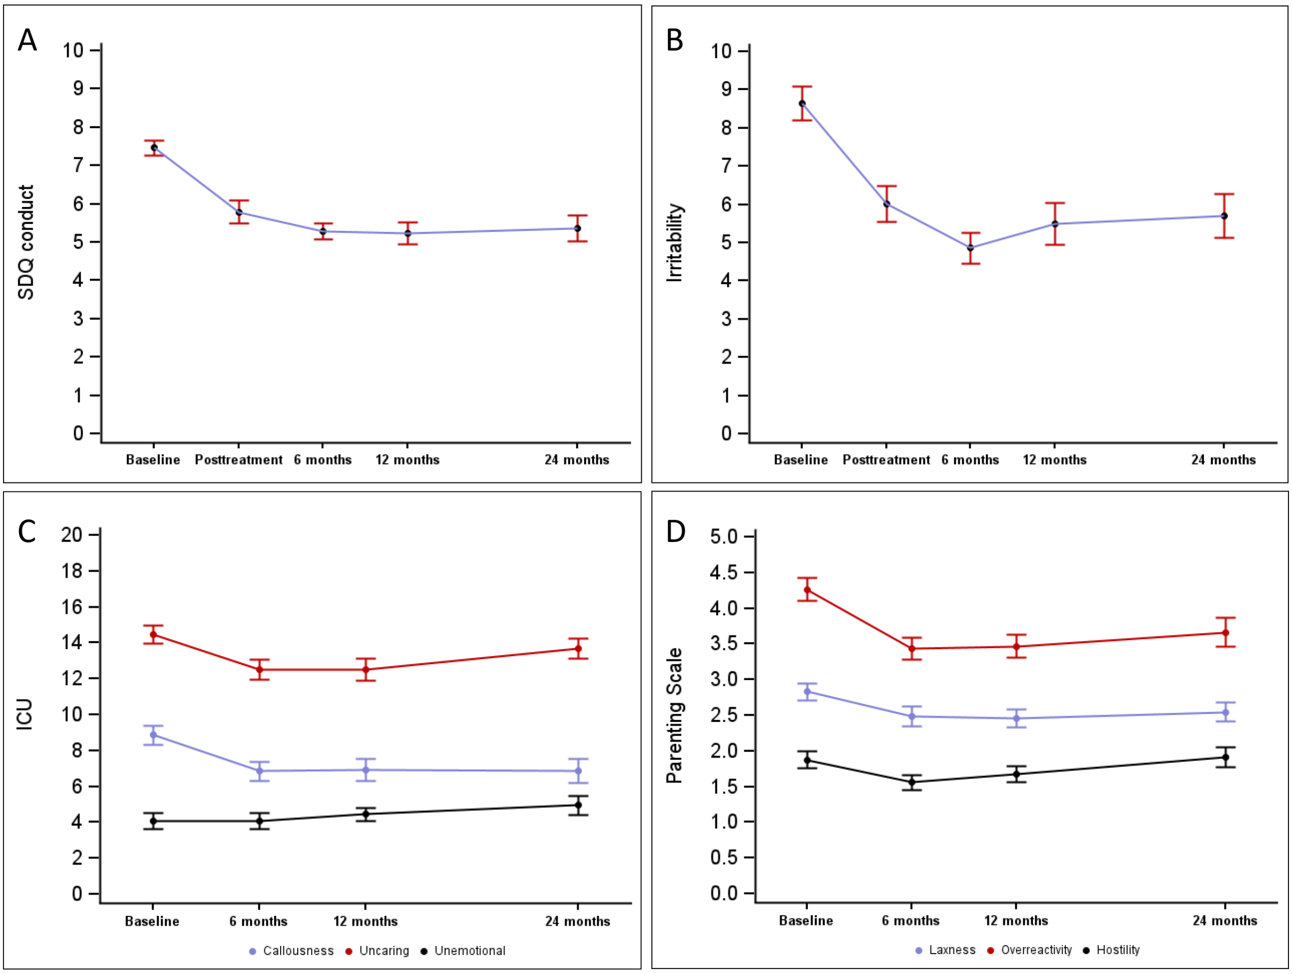
Among the child psychometric measures, callousness and uncaring improved between baseline and the 12-month follow-up. However, uncaring deteriorated between the 12- and 24-month follow-up, and no significant improvement was found between baseline and 24 months. The SFSW parent training program did not have any significant positive association with unemotional traits at the 12- or 24-month follow-up.

Child functioning in everyday situations (eg, transitions, dining, and home and outside home activities) improved significantly between baseline and both follow-up points. No significant change was observed between the 12- and 24-month follow-up comparisons.

Interestingly, there were differences between parenting styles regarding the long-term changes. Parental overreactivity and laxness improved between baseline and the 12-month follow-up and between baseline and the 24-month follow-up. Parental hostility showed improvement between baseline and the 12-month follow-up but not between baseline and the 24-month comparison. In fact, hostility showed significant deterioration between the 12- and 24-month follow-up. We observed no significant association in parental mental health problems, measured with a 21-item Depression, Anxiety, and Stress Scale, between baseline and either of the follow-ups.

Finally, to graphically illustrate the key findings, Figure 1A-D describes the changes of main outcome measures across time points including posttreatment and at the 6-month follow-up, which has previously been reported in detail [12]. Of note, the PS and ICU were not measured at posttreatment. The figures illustrate that SDQ conduct and ARI irritability scores exhibited the largest improvement between baseline and posttreatment and further improvement between posttreatment and the 6-month follow-up; the findings at the 12- and 24-month follow-ups were rather stable. Among the ICU measures, callousness and uncaring showed improvement between baseline and the 6-month follow-up. After that, callousness stayed quite stable, while uncaring and unemotional showed deterioration. As for the parenting measures, all parenting styles showed improvement between baseline and the 6-month follow-up. After that, overreactivity and laxness were quite stable, while hostility showed deterioration.

Figure 1. (A-D) Mean curves of SDQ conduct scores, irritability scores, ICU scores, and Parenting Scale subscores. (A) SDQ conduct scores over time (model-based least-squares means, SE). (B) Irritability scores over time (model-based least-squares means, SE). (C) ICU subscales over time (model-based least-squares means, SE). (D) Parenting Scale subscores over time (model-based least-squares means, SE). ICU: Inventory of Callous-Unemotional Traits; SDQ: Strengths and Difficulties Questionnaire.



Discussion

Principal Findings

To the best of our knowledge, this is the first study on long-term follow-up of digital-guided parent training intervention among children referred to treatment from specialized care. The findings mostly complement the previously conducted 6-month follow-up study [12] by showing that the SFSW program was associated with significant improvements in children's externalizing symptoms (our primary outcome) at 12 and 24 months after baseline. Of note, most of the improvement took place between baseline and posttreatment assessment, and the level of externalizing problems showed stability from the 12- to the 24-month follow-up. This study's importance is in demonstrating that digital parent training with weekly remote phone coaching seems to lead to enduring improvements in disruptive behavior problems in children with severe disruptive behavior problems. The findings align with a 24-month follow-up study of the SFSW program [11,15-17], which was used as a preventive and early intervention among 4-year-old children, identified through national medical checkups [28]. However, since the target group was different, the level of disruptive behavior problems among the children in this study was much more severe [12], which suggests the promise of such interventions in supporting populations with different levels of symptom severity.

Most comorbidities such as hyperactivity, emotional and peer problems, and child functioning in everyday situations maintained their improvement from baseline to the 12- and 24-month follow-ups as well. Interestingly, the program seemed to have a very clear association with decreased irritability. This novel finding implies that some of the major effects of parent training may be associated with decreasing irritability in parent-child interactions; this requires further research.

For some problems, such as callous-unemotional traits, improvement was reported at the 12-month follow-up but not at the 24-month follow-up. Callous-unemotional traits characterize a specific subgroup of children exhibiting early starting, stable, and severe conduct problems. It has been argued that conventional parenting interventions frequently prove ineffective within this subgroup [29,30].

Another important finding was that the responses to the parent training program seemed to differ according to parenting styles. Improvements in parent overreactivity and laxness were shown both in the comparison between baseline and the 12- and 24-month follow-ups, while parental hostility improved until the 12-month follow-up, then deteriorated to the same level as at baseline. It could be interpreted that parental hostility is, in the long run, resistant to parent training programs. It is also possible that accumulated stressors during the COVID-19–related public health restrictions may have posed an additional strain on some parents' psychological resources [31-33] and on their ability to maintain positive approaches to their child.

There is limited research on the effects of parenting interventions on reducing parental hostility. Parental hostility can have broad impacts within the family, potentially disrupting the ability of one parent to maintain a positive relationship with their child [34]. There is a significant positive correlation between parent hostility and child aggression, indicating that the more hostile parents are toward others, the more aggressive their children tend to be [35]. Similar findings regarding conduct problems, callous-unemotional traits, and parenting were made in a previous study [36], where higher levels of parental harshness were related to higher levels of child conduct problems and callous-unemotional traits. Children subjected to abuse resulting from their parents' aggressive behavior may experience adverse effects on their self-control and exhibit challenges in impulse control by acting impulsively, speaking before thinking, and demonstrating a reduced capacity to tolerate frustration or cope with failure [37]. There are also findings showing that parental attitudes play a substantial role in the gradual enhancement of a child's self-control, exerting a significant impact on the individual [35]. In cases where parent training proves to be ineffective in the long term in reducing parental hostility, the parent could benefit from receiving personal support or therapy to address this issue. It is likely that more tailor-made and targeted interventions and treatment plans would benefit this subgroup of families, which are at risk of falling into this kind of negative cycle.

When the study started in May 2020, Helsinki was grappling with the peak of the COVID-19 pandemic, marked by a state of emergency declared nationwide in Finland. Stringent social distancing measures were enforced in the region to curb the virus's transmission, significantly affecting families residing in the area. The COVID-19 pandemic has highlighted the importance of exploring remote, digital, or digitally assisted solutions for ensuring that young children, and their families, are provided with prompt support for mental health problems. This study demonstrated that technology can provide effective alternatives to traditional face-to-face interventions and can overcome a number of barriers during crises. Technology can be used to provide the right treatment at the right time, with high levels of support and fidelity, providing greater access and convenience and requiring fewer costs and less time.

Limitations

It is important to acknowledge certain limitations. The present results from our clinical sample do not necessarily generalize across community samples. Since no a priori power analysis was performed, we cannot exclude the possibility that the study was underpowered. We note that with a sample size of 50 participants, we had 80% power to detect an effect size of 0.35 (1-tailed, α=.05). The study design did not allow for direct conclusions regarding the program's efficacy, as it lacked an intervention-control group design. However, the COVID-19 pandemic meant that treatment and family counseling services could not be provided in the usual way, and conducting a randomized controlled study design would have been considered ethically inappropriate. Due to the lack of a control group, it is not possible to exclude the possibility of some age-related spontaneous improvement reflected in the results. Nevertheless, an earlier RCT using population-based screening in Finland showed that the SFSW intervention was effective at 2-year follow-up [11]. Furthermore, the constraints of social distancing, which included school closures, also prevented us from conducting direct observations of parenting, clinical assessments, and teacher ratings. It is possible that some consequences of those restraints are also reflected in some of our measures, such as the SDQ prosocial and peer subscales.

Conclusions

This study provides support for the utility of remotely delivered parent training interventions. Incorporating remote interventions into child mental health services also serves as a safeguard during crisis situations such as COVID-19.

The study shows that remote digital child mental health services bring substantial benefits to families that can last for up to 2 years. Overall, the study emphasizes that guided digital parent training programs can be a crucial component in developing evidence-based treatment practices for children and families.

The study also emphasizes the importance of conducting long-term follow-ups to understand long-term intervention gains. The study results indicate that different parenting profiles and child psychopathology may have varying effects on the long-term outcome of the program. This finding is important when developing personalized parenting interventions for increased impact.

Acknowledgments

The authors extend their gratitude to the head of Helsinki Family Counselling Centers, Leena Lehikoinen, and all the other professionals from the family counseling centers in Helsinki who contributed to making this study possible. This project has received funding from the European Research Council under the European Union's Horizon 2020 research and innovation program (grant agreement 101020767) and from the Research Council of Finland (decision 345546).

Conflicts of Interest

AS is the founder and director of Digifamilies, a provider of evidence-based treatments to Finnish public health services. AB received grant funding from The Israel National Institute for Health Policy Research, the National Institutes of Health, and the Israeli Scientific Foundation. He also provides consultancy services to ifeel. The remaining authors have no conflicts of interest to disclose.

Abstract

Background: Autism spectrum disorder (ASD) can have traits that impact multiple domains of functioning and quality of life, which can persevere throughout life. To mitigate the impact of ASD on the long-term trajectory of an individual's life, it is imperative to seek early and adequate treatment via scientifically validated approaches, of which applied behavior analysis (ABA) is the gold standard. ABA treatment must be delivered via a behavior technician with oversight from a board-certified behavior analyst. However, shortages in certified ABA therapists create treatment access barriers for individuals on the autism spectrum. Increased ASD prevalence demands innovations for treatment delivery. Parent-led treatment models for neurodevelopmental conditions are effective yet underutilized and may be used to fill this care gap.

Objective: This study reports findings from a retrospective chart review of clinical outcomes for children that received parent-led ABA treatment and intends to examine the sustained impact that modifications to ABA delivery have had on a subset of patients of Montera, Inc. dba Forta ("Forta"), as measured by progress toward skill acquisition within multiple focus areas (FAs).

Methods: Parents received ≥40 hours of training in ABA prior to initiating treatment, and patients were prescribed focused (<25 hours/week) or comprehensive (>25 - 40 hours/week) treatment plans. Retrospective data were evaluated over ≥90 days for 30 patients. The clinical outcomes of patients were additionally assessed by age (2-5 years, 6-12 years, 13 - 22 years) and utilization of prescribed treatment. Treatment encompassed skill acquisition goals; to facilitate data collection consistency, successful attempts were logged within a software application built in-house.

Results: Improved goal achievement success between weeks 1 - 20 was observed for older age, all utilization, and both treatment plan type cohorts. Success rates increased over time for most FAs, with the exception of executive functioning in the youngest cohort and comprehensive plan cohort. Goal achievement experienced peaks and declines from week to week, as expected for ABA treatment; however, overall trends indicated increased skill acquisition success rates. Of 40 unique combinations of analysis cohorts and FAs, 20 showed statistically significant positive linear relationships ($P<.05$). Statistically significant positive linear relationships were observed in the high utilization cohort (communication with $P=.04$, social skills with $P=.02$); in the fair and full utilization cohorts (overall success with $P=.03$ for the fair utilization cohort and $P=.001$ for the full utilization cohort, and success in emotional regulation with $P<.001$ for the fair utilization cohort and $P<.001$ for the full utilization cohort); and in the comprehensive treatment cohort (communication with $P=.001$, emotional regulation with $P=.045$).

Conclusions: Parent-led ABA can lead to goal achievement and improved clinical outcomes and may be a viable solution to overcome treatment access barriers that delay initiation or continuation of care.

Introduction

Autism spectrum disorder (ASD) impacts multiple domains of functioning and quality of life, which can persevere through an individual's lifetime [1,2]. These impacts span an individual's interpersonal relationships; intrapersonal experience and well-being; family finances; and parental stress [3-5]. Mitigating the impact of ASD on the long-term trajectory of an individual's life and the immediate familial well-being requires early and adequate treatment. Applied behavior analysis (ABA), a gold-standard treatment for ASD, employs scientifically validated and evidence-based approaches to foster skill acquisition across varying domains [6-8]. ABA is typically prescribed within the patient's treatment plan as comprehensive (treatment intensity ~25 - 40 hours/week) or focused (treatment intensity ~10 - 25 hours/week) treatment [9,10], as determined by a board-certified behavior analyst (BCBA). ABA treatment can be delivered via a behavior technician (BT) meeting age, education, and training requirements (>40 training hours) with BCBA oversight [9].

Although treatment success for ABA has extensive documentation in literature, this treatment approach suffers from several challenges that impede access and implementation [6-8]. Shortages in the BT and BCBA workforce result in difficulties with access and wait lists, particularly for individuals residing in remote geographical areas, leading to treatment delays [11-13]. Although the Behavior Analyst Certification Board (BACB) provides general guidelines, the traditional ABA model lacks a standard approach, as treatment plans need to be individualized. With the prevalence of ASD growing continually over the past several decades, expanding ABA access is necessary to ensure that individuals on the autism spectrum can develop and master social, emotional, and daily living skills [13].

The proximity of parents and/or caregivers (hereinafter referred to as “parents”) to individuals on the autism spectrum within daily living environments presents an opportunity to supplement or deliver naturalistic ABA treatment. In fact, many health insurance companies require a parent component (eg, participation in treatment) in order to ensure that treatment progress can be generalized in different settings [14]. Parent-led therapies have the added benefit of eliminating barriers such as wait lists and scheduling difficulties that occur with ABA treatment in clinical settings. Research has validated the effectiveness of parent-led therapies/interventions for ASD and other neurodevelopmental disorders [11,15-21]. Heitzman-Powell et al used a virtual platform to train parents in geographically remote areas to deliver ABA, after which parents gained an average of >39% increase in ABA knowledge; their successful ABA implementation also increased by >40% [11]. Molnár et al examined a parent-delivered early intensive behavioral intervention (EIBI), a form of ABA, and observed improvements in outcomes across different metrics [22]. Oono et al conducted a systematic review of trials examining parent-led interventions for children on the autism spectrum, and they found statistically significant improvements in language/communication and a reduction in ASD severity [23].

Our study contributes to the body of research on patient outcomes resulting from parent-led ABA. However, our work stands out from most prior work on parent- or caregiver-delivered ABA, as we present the outcomes of sustained real-world treatment outside of a research setting, which has the downside of a defined and relatively short study period. Our previous pilot study [18], which is related to this work, examined how nontraditional ABA modalities benefitted patient outcomes compared to traditional ABA. In this work, we report upon the sustained impact that modifications to ABA delivery have had on a subset of patients of Montera, Inc. dba Forta (hereinafter, “Forta”). Particularly, we describe how individuals receiving parent-led ABA treatment progressed toward goal achievement in terms of skill acquisition within multiple focus areas (FAs). Notably, this study is not a research trial study, but rather a retrospective chart review reporting on clinical outcomes of patients in parent-led ABA treatment.

Methods

Overview

Active patients of Forta between October 2022-May 2023 with a diagnosis of ASD per the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) diagnostic criteria [24] were considered for the study. Patients with incomplete documentation of goal progress and without a minimum of 90 days of data were excluded. The 90-day threshold ensured patients would be at least halfway through a typical 6-month ABA treatment plan. This resulted in 30 patients with sufficient data for analysis, as shown in the attrition chart (Figure 1). Patients included in the data analysis had available longitudinal data ranging from 15 - 20 weeks. Variation in available data resulted from patients initiating treatment with the company at different time points. Prior to treatment delivery, parents of patients completed ≥40 hours of ABA training using a virtual, web-based program adhering to BACB standards [25]. After training, the parents were required to pass an Initial Competency Assessment to demonstrate the skills and knowledge required to deliver ABA treatment. Upon successfully passing the Initial Competency Assessment, the parents became BTs and were assigned to a BCBA for supervision of the treatment process in accordance with the BACB guidelines [25]. Unlike typical BTs that deliver ABA treatment to more than one patient during a given week, the parents that became BTs focused on leading treatment delivery solely for their own children.

Demographics for the 30 patients whose data were processed and analyzed are displayed in Table S1 in Multimedia Appendix 1. Demographic data were obtained from ABA treatment patient intake forms completed by parents. The average patient age was 8.39 years (aged 2.81 - 22.60 years at the start of their data collection), and 77% (23/30) of the patients were males. Within the total patient cohort, 2 patients had syndromic ASD (both with DiGeorge syndrome, mild ASD, took no medication) and 28 patients had nonsyndromic ASD, where syndromic versus nonsyndromic ASD was defined according to Genovese and Butler [26]. At the beginning of the study, 14 patients took no medication, 3 were administered nonprescription medication or supplements (eg, antihistamines, multivitamins, probiotics, melatonin), 5 were administered antipsychotics, and 8 were administered prescription medication other than antipsychotics (eg, stimulants for attention-deficit/hyperactivity disorder, replacement hormones, anticonvulsants). We are not aware of any medication changes during the course of the study.

Patients were grouped by utilization of the number of ABA treatment hours that were prescribed by the BCBA who conducted the intake assessment and provided treatment oversight (Figure 1). To determine each utilization cohort, utilization data for each patient were averaged over their individual studied time period (≥15 weeks) and that average was used to classify each patient as having fair, full, or high utilization. The high utilization patient cohort completed ≥95% of the prescribed ABA treatment hours; the full utilization patient cohort completed 80% to <95%; and the fair utilization patient cohort completed <80%. Patients were assessed within three age cohorts (2.00 - 5.99 years, 6.00 - 12.99 years, and 13.00 - 22.99 years) and by their assignment to a focused (<25 hours/week) or comprehensive (>25 to 40 hours/week) ABA plan (Figure 1). The age cohorts align with existing research examining effects of ABA treatment across various ages [27].

The patient age distribution in each utilization cohort is shown in Figure 2A. There were 11 patients in the high utilization cohort (received ≥95% of prescribed treatment), 11 patients in the full utilization cohort (received 80% to <95% of prescribed treatment), and 8 patients in the fair utilization cohort (received <80% of prescribed treatment). Figure 2B displays overall utilization rate trends for all patients within each utilization cohort. Weekly utilization was averaged on a weekly basis for each patient and represents the percentage of prescribed weekly ABA treatment hours that patients utilized during the study. Previous studies indicated that utilization of >80% of prescribed ABA hours can be regarded as a “full dose” of ABA treatment (ie, full utilization) [28,29].

Following the intake assessment, the BCBA provided each patient with a highly individualized treatment plan establishing specific goals for skill acquisition based on that individual patient’s strengths and weaknesses across multiple FAs. For complex skill acquisition goals, goals were broken down into multiple treatment targets for the patient to master the entire goal. For example, within the communication domain, if a patient was prescribed the skill acquisition goal of “identifying common objects,” the patient could be further assigned the targets of “identifying a chair” and “identifying a cup” to work on. The process of mastering each goal involved the patient working on one or more targets associated with that specific skill acquisition goal. On average, patients in the analysis cohort worked on 21.1 skill acquisition goals and associated targets during the study period.

To measure clinical outcomes for each patient, the study solely evaluated skill acquisition goals. Patient progress toward mastering a particular skill was assessed with quantifiable parameters (ie, number of successful attempts to complete a task). This evaluation served as an indicator of the patient’s level of achievement toward a specific goal, a measurement technique that may be better suited to indicate clinical progress and outcomes than standard of care assessments [30]. The goal achievement data are reported as the percentage of successful attempts to complete a task out of all attempts, reported as percent of trial data. The goal achievement data were averaged weekly for each patient for each skill acquisition goal they worked on during that week. Goal achievement data are expressed as a percentage value ranging from 0% (0 successful attempts) to 100% (all attempts were successful). This is a method similar to that used by Choi et al, in which patient progress in ABA treatment was measured by the desired percent of goals versus actual goals achieved [31].

Baseline data for each skill acquisition goal for each patient were collected either by BCBA or parent assessment. This provided the opportunity for the BCBA to personalize the treatment plan and progress measurement. Longitudinal goal achievement data for each patient were logged for each skill (subsequent to baseline data measurement for that particular skill) by the parent BT during the course of ABA treatment sessions on a software application built in-house. This application facilitated streamlined data collection and analysis. Following the creation and implementation of a treatment plan, specific goals were tracked on the application, which provided a user-friendly interface for parent BTs to log session data, while having the additional benefit of ensuring a robust and streamlined data collection and analysis process. During a treatment session, parent BTs could select a specific skill acquisition goal or target thereof from the assigned treatment plan and report the total number of attempts and how many were successful. As data were easily accessible, parent BTs could review data after the treatment session to complete notes and progress reports. The application also provided a user-friendly mechanism for the BCBAs to track progress over time and ensure the most pertinent skill acquisition goals were being implemented and evaluated. Data for the analysis in this study were collected through the application, encompassing the data for all skill acquisition goals across all treatment sessions for the 30 patients with ≥90 days of data. With direct clinical data, there is a limitation on interrater reliability, as each patient was only evaluated by a single practitioner providing therapy (ie, their parent BT). However, our treatment delivery methods were evidence-based (eg, skill acquisition via manding [a request for a want or need], reinforcement, task analysis) and BCBAs performed ongoing supervision sessions with parent BTs and patients, thereby monitoring overall progress to ensure treatment was administered effectively and within the ABA standard of care [9]. Parent BTs performing ABA treatment were supervised by a BCBA for at least 5% of the treatment time (according to the BACB requirement) [25], or for any amount of treatment time required by state or insurance regulations [32-36].

For data analysis, we grouped skill acquisition goals into 4 FAs or categories: communication (COM), emotional regulation (ER), executive functioning (EF), and social skills (SS). Each FA aligned with a corresponding domain or subdomain utilized in the Vineland Adaptive Behavior Scale, 3rd Edition (Vineland-3), a widely used assessment tool targeting neurodevelopmental disorders, as follows [37]. COM FA corresponds to the Vineland COM domain; ER FA to the Coping Skills subdomain (Socializing domain); EF FA to the Daily Living Skills domain; and SS FA to the Vineland Interpersonal Relationships and Play and Leisure subdomains (Socializing domain). Vineland-3 domains and subdomains were used strictly for mapping the FAs (ie, assigning every skill acquisition goal to an FA) and were not employed as a data assessment scale for the data reported in this paper.

To evaluate the progress of patients and compare different cohorts, patients were first grouped into utilization rate, age groups, and treatment plan type cohorts. Within each group, goal success rate was measured across all skill acquisition goals and across each FA across cohorts (eg, success rate of all ER goals across all patients with a comprehensive care plan) for each patient. To evaluate the progress of goals over time, a correlation coefficient was computed for each FA for each cohort to determine the magnitude of change and the direction of the success rate trend for each cohort. A statistical significance test was then performed across all patient cohorts to determine if the correlation coefficient (*r*) was significant, indicating the change in performance over time did increase over the evaluation period of 16 weeks (Table 1).

Figure 1. Attrition chart. Figure created using Lucidchart [38].

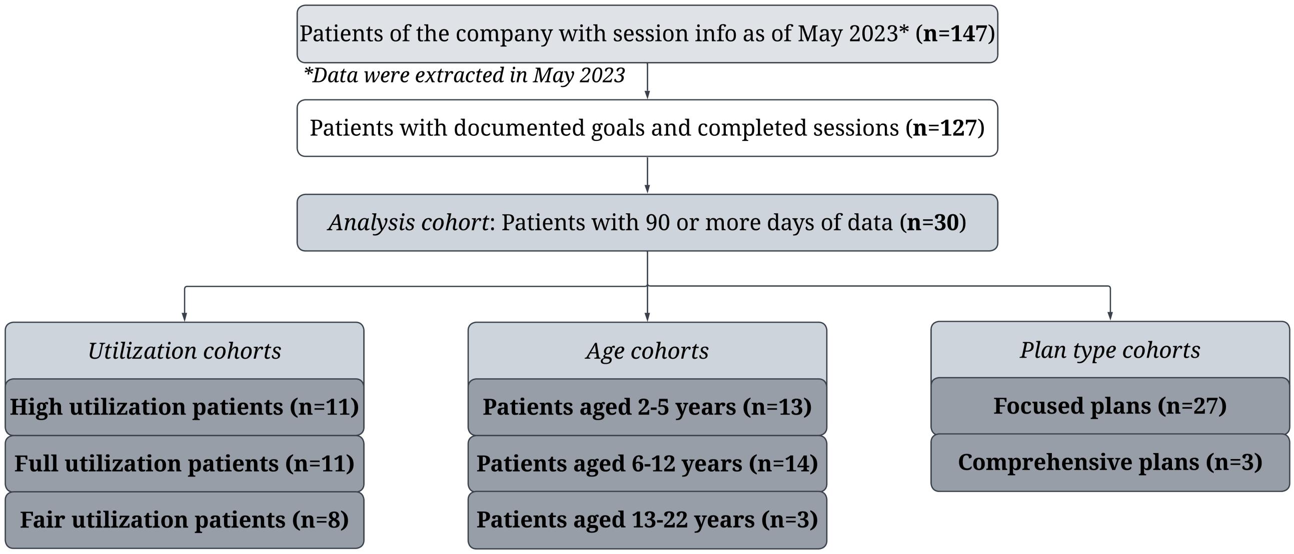

Figure 2. High utilization cohorts by (**A**) age and (**B**) weekly utilization. Goal achievement/success rate by utilization (**C**) overall and (**D**) for each focus area. Black lines aggregate all patients; each gray line represents a single patient; a vertical dashed line at 13 weeks denotes the cutoff for the minimum amount of data that each patient was required to have for inclusion in the study. This figure was created using Plotly in Python.

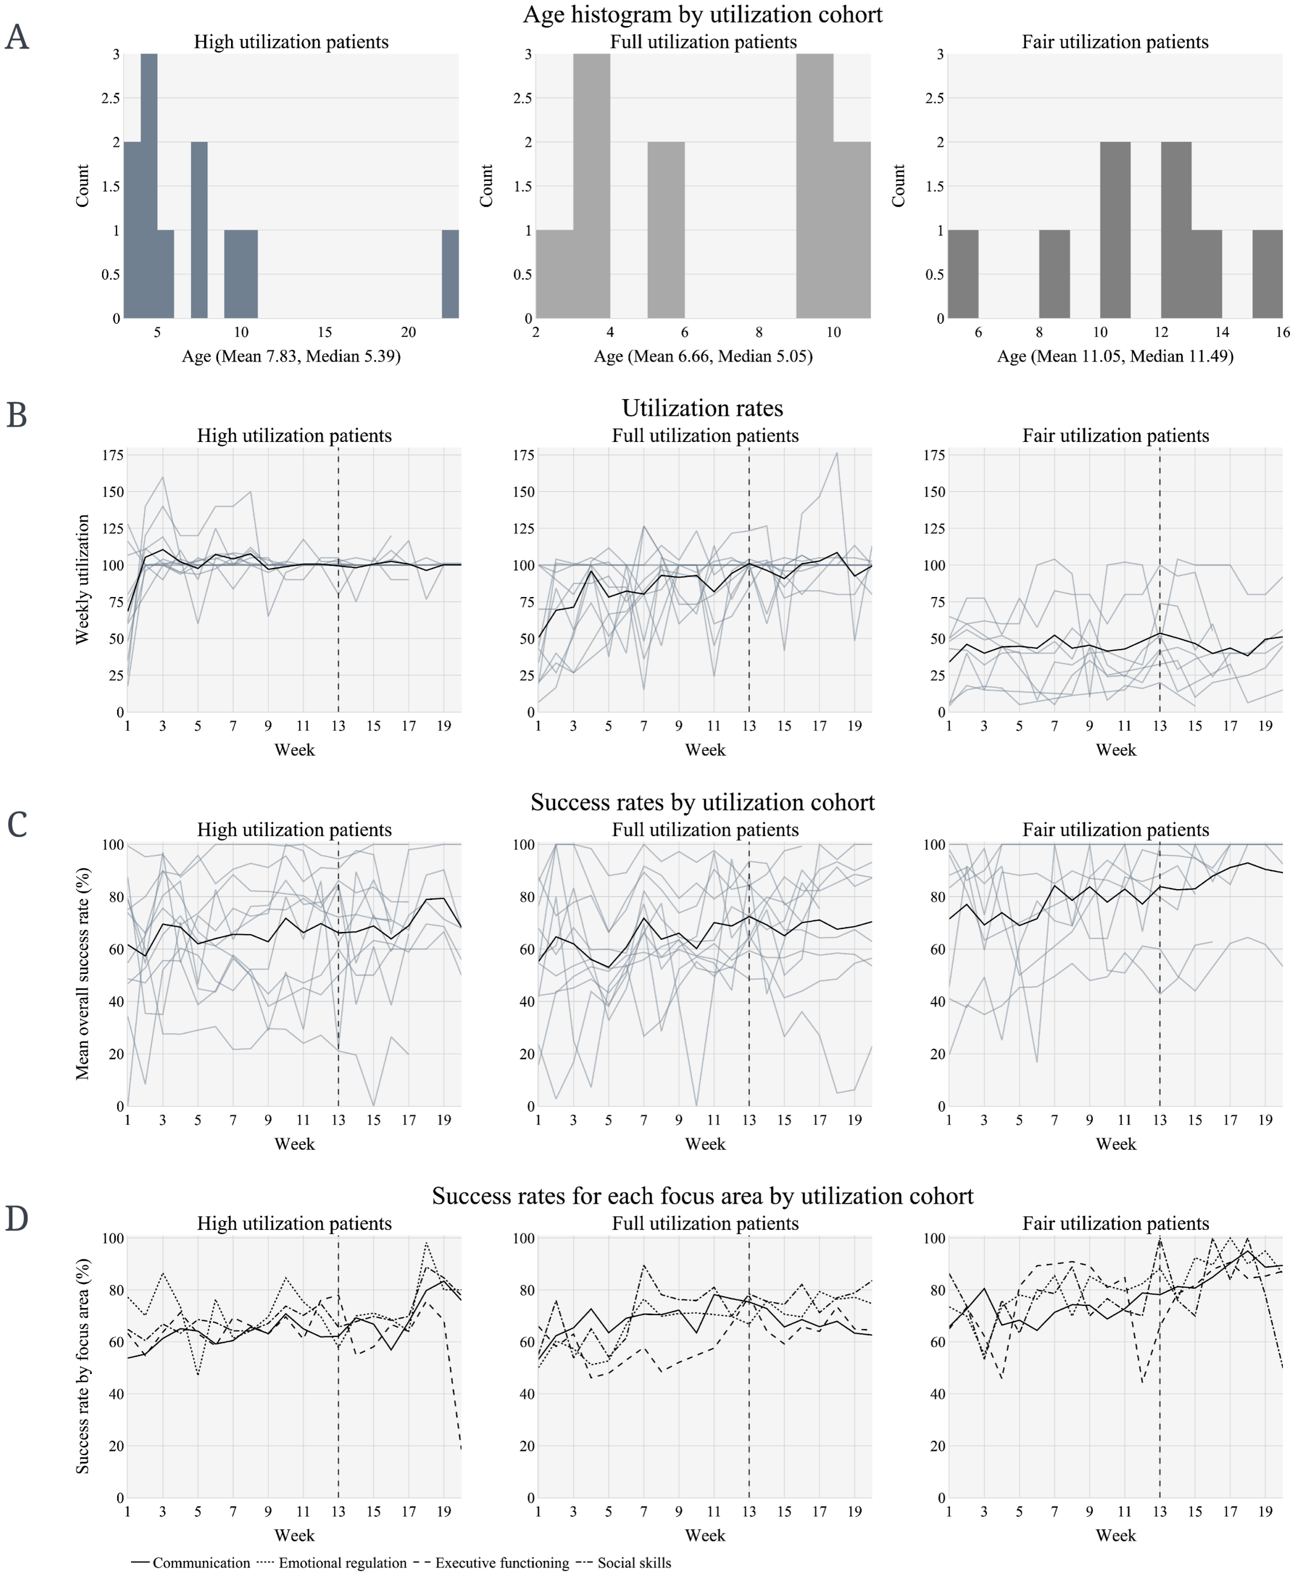

Table . Summary table indicating the net change in success rate overall and across each focus area for the different utilization, treatment plan type, and age cohorts (weeks 1 ‑ 16).[a]

		Utilization cohorts			Treatment intensity cohorts		Age cohorts (years)		
		High (n=11)	Full (n=11)	Fair (n=8)	Focused (n=27)	Comprehensive (n=3)	2 ‑ 5 (n=13)	6 ‑ 12 (n=14)	13 ‑ 22 (n=3)

Ethical Considerations

This work was deemed exempt by an independent Institutional Review Board per Food and Drug Administration 21CFR56.104 and 45CFR46.104(b)(4) and received a waiver of informed consent. The work was carried out in accordance with ethical standards and with the Declaration of Helsinki (revised in 2000). Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guidelines have been applied in this study.

Results

Overview

Results are shown for goal achievement progress between weeks 1 (start of data collection) and 20. All patients had available data for the initial 13 weeks of the study and a minimum of 90 days of data total. All selected patients had >15 weeks of data (29 patients with ≥16 weeks, 1 patient with 15 weeks). The data between weeks 16 - 20 were less robust, as each patient had a different longitudinal dimension in that time period of data analysis, with some patients having only 16 weeks of data, and others having the full 20 weeks.

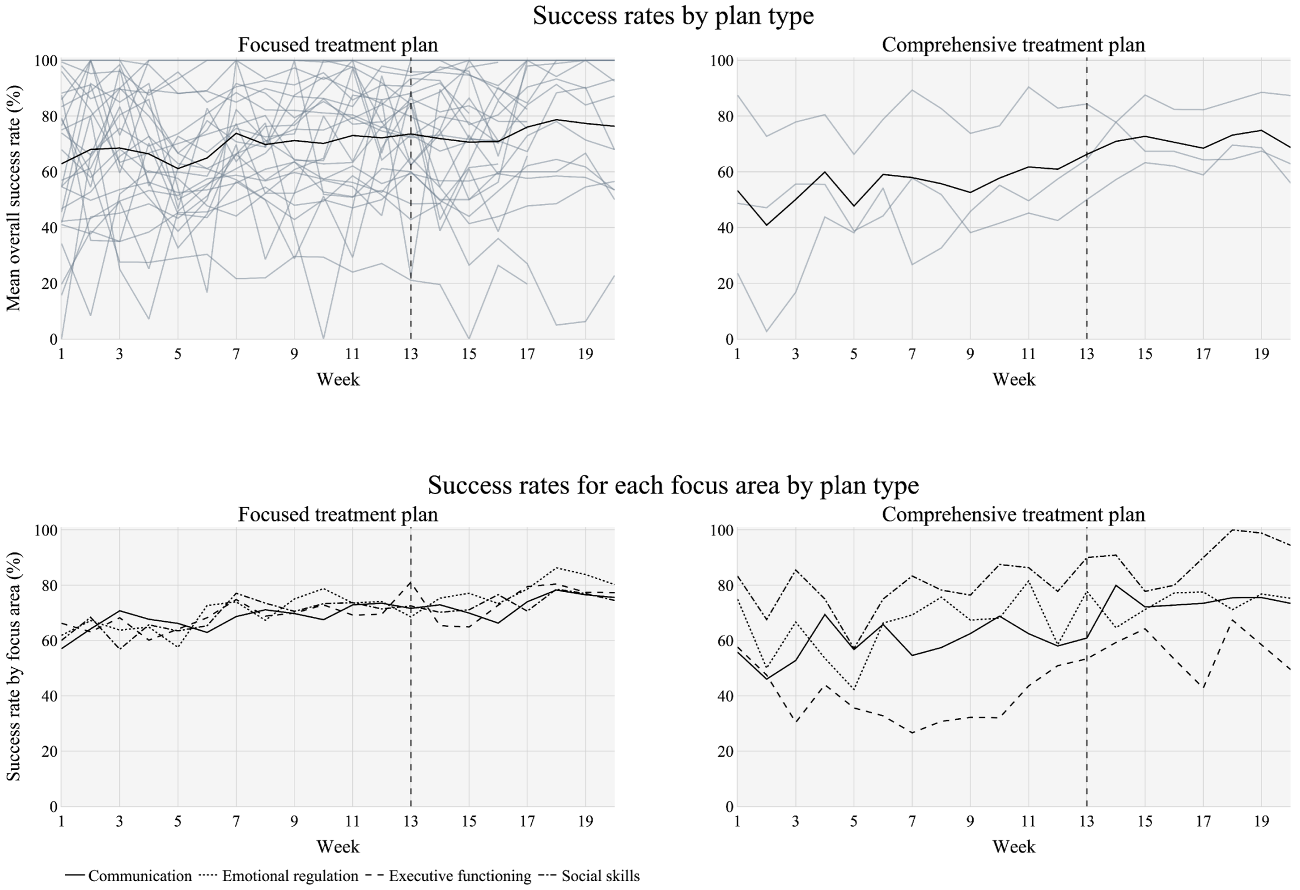
Goal Achievement/Success Rate by Utilization Rate and FA

As shown in Figure 2C, overall success toward skill acquisition increased for all 3 utilization cohorts. Overall success rate appears to be consistent and shows improvement over the 20-week period across all utilization cohorts. When examining the success rate for each FA by utilization cohort for the initial 16-week period, patients in each utilization cohort displayed growth in all 4 FAs, except ER for the high utilization cohort, which varied significantly during this period (Figure 2D). From weeks 16 to 20, patients in the high utilization cohort showed a distinguishable increase in success rate in ER, while remaining highly variable. In addition, patients in the high utilization cohort showed a drop in success for EF from weeks 19 to 20 after a steady increase during the initial 19 weeks. Further, patients in the fair utilization cohort displayed a substantial drop in success rate for SS from weeks 18 to 20, after having increased during the initial 18 weeks. Notably, EF and SS exhibited high variability.

Goal Achievement/Success Rate by Treatment Intensity (Plan Type) and FA

For patients in both treatment plan types, growth over time was displayed in the overall success toward skill acquisition (Figure 3, top panels). Success rates for each FA by treatment intensity (Figure 3, bottom panels) followed largely the same trend as the overall success rate (Figure 3, top panels), except EF for the comprehensive treatment plan cohort. Patients prescribed a focused treatment plan displayed consistent and similar growth in success rates over time for all 4 FAs. Patients prescribed a comprehensive treatment plan displayed growth in success rates over time in COM and SS. The success rate for ER and EF showed great variability for the comprehensive treatment plan cohort. However, this trend may be due to a smaller sample size (n=3) compared to the patient cohort prescribed a focused treatment plan (n=27).

Figure 3. Goal achievement/success rate by treatment intensity: overall (top panels) and for each focus area (bottom panels). Black lines aggregate all patients; each gray line represents a single patient; a vertical dashed line at 13 weeks denotes the cutoff for the minimum amount of data that each patient was required to have for inclusion in the study. This figure was created using Plotly in Python.



Goal Achievement/Success Rate by Age Cohort and FA

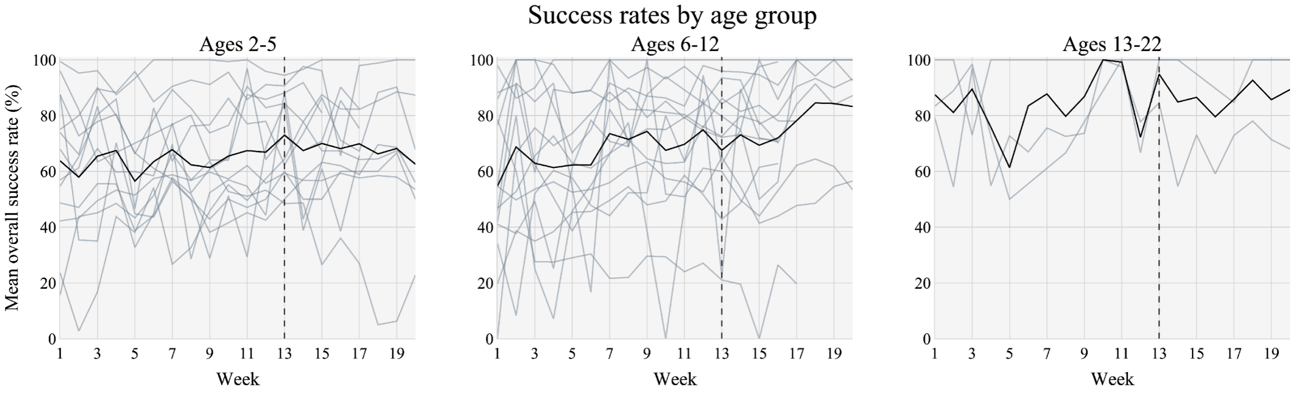
As shown in Figure 4 (top panels), overall success toward skill acquisition varied among the 3 age cohorts, with the most notable growth over time for the middle age cohort (6 - 12 years), followed by more modest growth for the oldest age cohort (13 - 22 years). The youngest age cohort (2 - 5 years) displayed growth for the initial 16-week period, where data were present for all but 1 patient. After 16 weeks, less data were available for the youngest and middle age cohorts; thus, statistical significance (as denoted by *P* value and *r*) of the results decreased by comparison with the initial 16-week period. Results after week 16 did not demonstrate statistical significance. The success rates for each FA by age cohort (Figure 4, bottom panels) followed largely the same trend as the overall success rate observed in Figure 4, top panels. The most notable and consistent growth over time was observed for the middle age cohort (6‑12 years) for all 4 FAs. When examining data for the oldest age cohort (13‑22 years) for each FA, no discernible pattern emerged; however, data appear to indicate a trend of increased performance with increasing treatment time. The youngest age cohort (2‑5 years) demonstrated growth for the initial 16-week period for COM, ER, and SS, with ER and SS maintaining growth after 16 weeks. The youngest age cohort struggled the most with EF. It is notable that 3 of the 13 patients in the youngest age cohort have been prescribed a comprehensive treatment plan, and that the EF FA displays the same trend with respect to the other 3 FAs for the comprehensive treatment plan cohort and for the youngest age cohort.

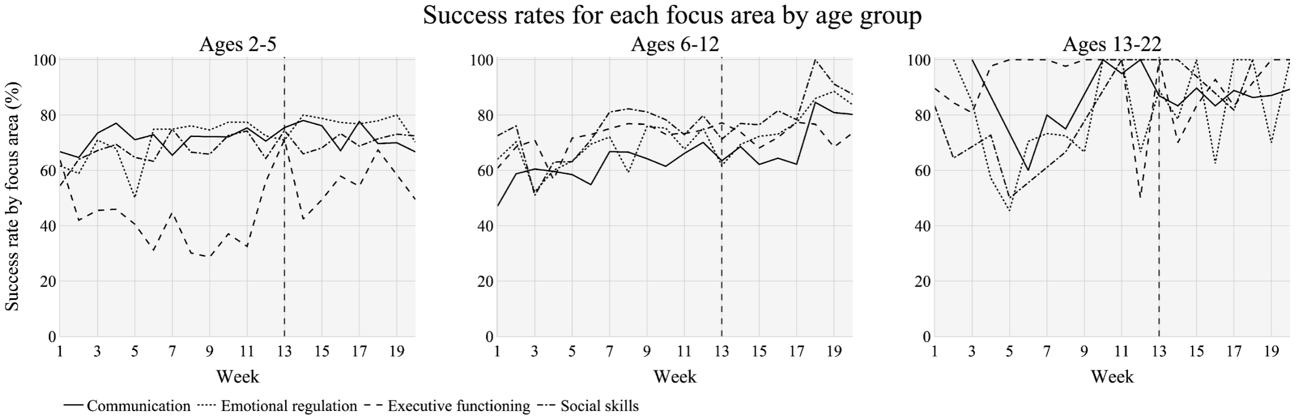
The results in Table 1 indicate the severity breakdown for each analysis cohort, as derived from DSM-5 severity level criteria, and the correlation coefficient (*r*) and *P* value for the cohort's success rate across each analysis cohort. The correlation coefficient represents the strength of the relationship of the cohort's success rate over time, with values closer to −1/1 indicating a stronger negative/positive relationship in success rate over time, and values closer to 0 indicating a flatter relationship over time. The corresponding *P* value indicates the likelihood of the relationship being flat (slope of a regression line equal to 0). For each analysis cohort, these values were computed across each FA, as well as overall (ie, in combination across all FAs).

Of the 40 unique combinations of analysis cohorts and FAs (Table 1), 20 showed statistically significant positive linear relationships (*P*<.05), with 26/40 having *r*>0.4, indicating at least a moderate-to-strong positive linear relationship in the data and 35/40 having *r*>0.2, indicating at least a weak-to-moderate positive linear relationship [39].

The mean age of patients between the treatment intensity cohorts indicates that patients with comprehensive treatment plans are younger than patients with focused plans, with all 3 patients in the comprehensive cohort being in the age range of 2‑5 years old. In addition, the youngest age cohort also had the highest mean number of authorized hours, with 3 of the 13 patients prescribed a comprehensive treatment plan. This aligns with literature indicating that younger children will gain more in ABA treatment with more hours [40]. Patients with comprehensive plans also had higher mean utilization, indicating not only a more intensive treatment plan, but also a more intense implementation of the treatment plan. Similarly, younger patients also have substantially higher utilization rates than older patients.

Figure 4. Goal achievement/success rate by age cohort: overall (top panels) and for each focus area by age (bottom panels). Black lines aggregate all patients; each gray line represents a single patient; a vertical dashed line at 13 weeks denotes the cutoff for the minimum amount of data that each patient was required to have for inclusion in the study. This figure was created using Plotly in Python.





Discussion

Principal Findings

This study examines outcomes for a small sample of Forta's patients receiving parent-led ABA treatment, where half of the cohort combinations demonstrated statistical significance in regard to positive linear relationships for skill acquisition. Within all cohorts, we generally observed growth toward overall success for skill acquisition for all 3 utilization cohorts, with a few exceptions. Additionally, we observed variability in success toward skill acquisition over the study period. Use of success toward skill acquisition as an outcome measure fills a gap in the literature, as a majority of studies utilize standardized measurements, such as Vineland-3, which do not reflect the granular changes that can be observed with behavior changes [8,27]. This is of particular value in clinical settings, as these changes can guide individualized treatment planning.

Separation of patients by age (cohort 1: 2 - 5 years, preschool; cohort 2: 6 - 12 years, elementary and middle school; cohort 3: 13 - 22 years, high school and older) reflects research indicating that these 3 age groupings master different skills at different rates within ABA treatment. This is particularly true for younger children, for whom the number of treatment hours directly impacts success toward skill acquisition [27].

When stratified by utilization, all 3 cohorts generally experienced growth in skill acquisition. The variability in success with ER within the high utilization cohort could be the result of parents having to spend a significant amount of time getting patients to become receptive to treatment during a session (owing to patient struggles with ER and EF).

Within cohorts stratified by age, there were several statistically significant positive linear relationships observed for the middle age cohort in all FAs, which may indicate that these patients were more receptive to treatment. The youngest age cohort struggled with EF; however, attaining EF skills is known to be a complex process that may be impacted by subtle differences between individual patients [41]. This cohort was the only age cohort for whom progress in EF goals declined between the start and conclusion of the study, which could be attributed to a number of factors. For example, this age cohort had the most patients with a high level of symptom severity, which may have impeded progress toward EF skill acquisition. Progress may also have been hindered if parents had to spend a greater number of hours acclimating their children to the treatment process.

Regarding the variability from week to week for skill acquisition success, research indicates that progress toward skill acquisition in ABA treatment does not typically follow a steady progression; thus, variability is expected [8,19,37,40]. Observing such fluctuations within different FAs may help a parent decide which skill to focus on for a given day, depending on their child's success level [27]. Although we also detected this weekly variability, several FAs followed linear trends in terms of progress within each cohort. Regarding the linearity that was observed within the focused treatment cohort across all FAs, this demonstrated that fewer treatment hours (focused treatment plans have fewer hours than comprehensive ones) can also lead to linear skill gains. Our results indicate that fewer treatment hours can also be beneficial; however, according to the existing literature, a higher number of hours (ie, comprehensive treatment) provides for better outcomes in terms of skill acquisition in ABA for individuals on the autism spectrum [42]. Linstead et al noted that when treatment intensity was either high or low, individuals did not gain as much per hour as individuals who received an intermediate number of treatment hours [30]. These two literature findings [30,42] are not mutually exclusive and both support the notion that treatment plans have to be highly individualized to provide the basis for achieving the most beneficial treatment gains. The linearity of gains for the patients in the focused cohort may indicate that the focused plan was appropriately assigned for the 27 patients. Further, even with only 3 patients in the comprehensive cohort (not providing much opportunity for averaging out data outliers), COM and ER displayed statistically significant positive linear relationships (*P*<.05, Table 1), which may also indicate that the focused treatment plan was appropriately assigned for the 27 patients.

When the patients were stratified by treatment intensity (plan type), there was more variation in the level of skills within all focus areas at both the start and conclusion of the study in the comprehensive versus focused cohorts.

Data regarding broad average utilization based on either prescribed hours of treatment or insurance-approved hours of treatment are not publicly documented, to the best of our knowledge. Therefore, the utilization rates that we present in this clinical outcomes study will fill a gap in the literature. Within research studies of ABA treatment, rates of utilization are highly variable. However, variability in the use of prescribed ABA hours and underutilization of prescribed ABA hours, which may impact a patient's ability to receive the "full dose" of treatment (at least 80% of prescribed treatment hours), is not uncommon. In a study by Yingling et al, patients on the autism spectrum who were prescribed a specific number of weekly hours for EIBI treatment only used a mean of 37% of those hours and the authors further noted that the most utilization was observed within the first week of EIBI treatment [43], a pattern that was not observed within our patient cohorts. By contrast, our overall utilization in the analysis cohort (n=30) was 80.2%, which is over twice as high when compared with the utilization reported by Yingling et al [43]. Choi et al examined ABA treatment utilization and noted that 28% of the patient population received the "full dose" of treatment in terms of hours or sessions [44], in contrast to our study, in which 70% of the patients used the "full dose" of authorized treatment hours. Croen et al [29] studied an ABA-based behavioral health treatment in which underutilization of prescribed treatment hours was observed, with only 15% of patients receiving the "full dose" of prescribed treatment hours. These studies examined treatment in clinical settings (as opposed to treatment delivered in-home by parents), and there may have been barriers that were prohibitive for initiating and maintaining care, such as a nationwide shortage of ABA treatment providers [45] or geographical limitations and/or costs associated with travel to obtain treatment in clinical settings, which are mitigated in our treatment approach [11]. Differences between the high utilization of the prescribed hours in our study and relatively poor treatment adherence in other studies could also be attributed to the parents' increased confidence in their ability to successfully deliver ABA treatment resulting from the receipt of ABA training [21,46].

This research highlights the potential value of parent-led ABA treatment in terms of impacting a patient's success toward goal acquisition, particularly as it relates to overcoming financial and logistical burdens of gaining access to ABA [16]. These factors impede the ability to obtain and sustain treatment, which prevents patients on the autism spectrum from receiving validated treatment that may improve outcomes [15,45]. At the time the data were analyzed for this study, Forta had almost 200 patients, a number which has seen continued and substantial growth in a small window of time. This may reflect the need for more service providers, as well as the need for alternative ABA treatment delivery methods that afford greater flexibility (ie, in-home and parent-led) for parents and families, which may ensure treatment uptake and adherence. By training parents to deliver treatment to their children on their own schedule and without having to leave their homes, parents can continue treatment regardless of the availability of BTs to sustain the gains that their child makes toward skill acquisition. Additionally, by allowing the BCBAs to perform monitoring virtually, logistical barriers are eliminated and the BCBAs can use time that may otherwise have been used for travel to patients' homes to see more patients. Parent-led ABA further allows treatment to be delivered in a culturally appropriate manner, which is important for treatment outcomes [16,47].

Study limitations are as follows. First, our study did not account for variables beyond age, utilization, and treatment intensity. Research suggests that sociodemographic traits can impact the utilization of ABA, which may impact progress toward goal achievement [48]. The severity of symptoms and the parent's skills for treatment delivery may also impact treatment outcomes [42]. In our 2 youngest cohorts, a higher number of patients were diagnosed with moderate and severe ASD. Though these cohorts accessed a "full dose" of treatment (>80% of prescribed hours), the severity of symptoms may require more time in treatment to progress at a pace similar to older patients. Individuals with greater severity of symptoms may also start treatment with limited baseline skills, which may impact rate of progress [49]. Individuals with more severe symptoms may have lower treatment adherence [50], which may impact outcomes. Future work should examine the effect of diverse variables/factors on treatment progression. As parents recorded the progress of their child, there is the potential that response bias may have impacted the internal validity of results. Future examination of patient outcomes may use a more research-focused design, including a control group, randomization of treatment intensity, or a larger number of patients to demonstrate statistical significance, the latter which may also improve upon generalizability. Though our study examined outcomes over a longer period of time than our previous pilot study, observing outcomes over a sustained period of time may elucidate different skill acquisition patterns, as patients are known to demonstrate better achievement in some skills over a longer treatment period (as opposed to intensity) [30]. Measuring such changes may be facilitated by the use of standardized assessments such as Vineland-3. Therefore, future work can incorporate validated outcome measurements to determine larger-scale, longitudinal changes resulting from ABA [8,27]. Last, there was a very small number of patients in the oldest cohort (13 - 22 years), which may have prevented the emergence of clearer trends. This cohort also had the lowest utilization, which may be the result of resistance to therapeutic treatments among adolescents (and a greater level of health care decision autonomy), fear of autism-related social stigma [51,52], and/or social and academic obligations. To better understand the extent that outcomes can be impacted in adolescents and young adults, future work should include a greater number of individuals within that age range.

Conclusion

This retrospective chart review study explored longitudinal trends related to patients' success toward achieving skill acquisition goals in parent-led ABA therapy within a real-world treatment setting. We examined the clinical outcomes of patients receiving parent-led ABA and noted overall growth in success for most cohorts and FAs. This study demonstrated the potential for parent-led ABA treatment delivery as an alternative approach to traditional ABA delivery in a clinical setting.

Abstract

Background: Universal screening for depression and anxiety in pregnancy has been recommended by several leading medical organizations, but the implementation of such screening protocols may overburden health care systems lacking relevant resources. Text message screening may provide a low-cost, accessible alternative to in-person screening assessments. However, it is critical to understand who is likely to participate in text message–based screening protocols before such approaches can be implemented at the population level.

Objective: This study aimed to examine sources of selection bias in a texting–based screening protocol that assessed symptoms of depression and anxiety across pregnancy and into the postpartum period.

Methods: Participants from the Montreal Antenatal Well-Being Study (n=1130) provided detailed sociodemographic information and completed questionnaires assessing symptoms of depression (Edinburgh Postnatal Depression Scale [EPDS]) and anxiety (State component of the State-Trait Anxiety Inventory [STAI-S]) at baseline between 8 and 20 weeks of gestation (mean 14.5, SD 3.8 weeks of gestation). Brief screening questionnaires, more suitable for delivery via text message, assessing depression (Whooley Questions) and anxiety symptoms (Generalized Anxiety Disorder 2-Item questionnaire) were also collected at baseline and then via text message at 14-day intervals. Two-tailed *t* tests and Fisher tests were used to identify maternal characteristics that differed between participants who responded to the text message screening questions and those who did not. Hurdle regression models were used to test if individuals with a greater burden of depression and anxiety at baseline responded to fewer text messages across the study period.

Results: Participants who responded to the text messages (n=933) were more likely than nonrespondents (n=114) to self-identify as White (587/907, 64.7% vs 39/96, 40.6%; *P*<.001), report higher educational attainment (postgraduate: 268/909, 29.5% vs 15/94, 16%; *P*=.005), and report higher income levels (CAD $150,000 [a currency exchange rate of CAD $1=US $0.76 is applicable] or more: 176/832, 21.2% vs 10/84, 11.9%; *P*<.001). There were no significant differences in symptoms of depression and anxiety between the 2 groups at baseline or postpartum. However, baseline depression (EPDS) or anxiety (STAI-S) symptoms did predict the total number of text message time points answered by participants, corresponding to a decrease of 1% (e^{β}=0.99; *P*<.001) and 0.3% (e^{β}=0.997; *P*<.001) in the number of text message time points answered per point increase in EPDS or STAI-S score, respectively.

Conclusions: Findings from this study highlight the feasibility of text message–based screening protocols with high participation rates. However, our findings also highlight how screening and service delivery via digital technology could exacerbate disparities in mental health between certain patient groups.

Introduction

Perinatal Mental Health

Perinatal mood and anxiety disorders such as depression and anxiety are among the most common complications of pregnancy affecting as many as 20% of pregnant and postpartum individuals [1]. Failure to identify those at risk of adverse perinatal mental health outcomes can have negative consequences for both mother and child [2]. Maternal suicide is a leading cause of maternal death in high-income countries [3-5], while maternal prenatal depression and anxiety associate with an increased risk of preterm birth and low birth weight [6-9], child socioemotional and behavioral difficulties [10-17], and clinically significant psychiatric symptoms in adolescence and early adulthood [15,18-21]. Cost analyses from the United States, the United Kingdom, Australia, and Canada highlight the significant economic impact of untreated perinatal mood and anxiety disorders [22-25]. As such, the early detection and the appropriate treatment of maternal depression and anxiety are public health priorities [5].

Given the high prevalence and adverse consequences of perinatal mood and anxiety disorders, several countries now recommend universal screening for maternal depression and anxiety using validated questionnaires beginning in pregnancy [26-30]. In contrast, the Canadian Task Force on Preventive Health Care recently recommended against questionnaire-based screening [31], in part due to the time-consuming nature of these assessments. The use of brief screening instruments and remote screening approaches delivered using personal mobile devices may help overcome barriers to the implementation of universal screening for maternal perinatal depression and anxiety [32-34].

Mobile Health Perinatal Mental Health Screening

In Canada, approximately 96% of individuals aged 15 to 44 years own a smartphone [35], with comparable smartphone ownership rates in other countries including the United States [36]. The widespread availability of smartphone devices has led to increased interest in the use of personal mobile devices to deliver health care and public health services, termed "mobile health" (mHealth) [37,38]. mHealth encompasses a variety of approaches to identify, treat, or prevent adverse health outcomes including mental illness [39-46].

The most common mHealth approach is text messaging, which has been used for communication (eg, providing appointment reminders and improving patient adherence with treatment), intervention (eg, monitoring chronic conditions and providing psychological support), and patient data collection (eg, self-reported questionnaires screening for symptom levels) [39,47-51]. Text messaging allows for more timely and repeated self-report symptom capture with minimal burden [47]. A growing number of studies have used text messaging as a tool to collect self-report patient data in the perinatal period (pregnancy through 1 year postpartum) [40,52,53]. Studies in Canada and the United States have found text message–based mental health screening to be acceptable and feasible when compared to paper-based screening during the perinatal period [52-54], with increased participant satisfaction reflecting an increased perception of privacy and anonymity [52,54]. Few studies to date have examined potential selection biases (ie, sociodemographic and mental health factors) that may influence participation in a text message–based screening protocols [52]. In the United States, lower levels of participant engagement in digital health interventions were observed in racialized groups including Black and Latino communities [55]. To date, there are no Canadian reports on patient engagement in text message–based perinatal mental health screening particularly among racialized or low-income individuals [52,56-60].

In this study, we sought to identify factors that predict participation in a text message–based mental health screening protocol within a diverse, longitudinal cohort in Canada as a first step toward assessing the feasibility of using mHealth approaches to screen maternal mental health at the population level.

Methods

Ethical Considerations

Informed consent was obtained from all study participants, and the option to opt out of the study was provided to all participants. Ethics approval for the study was granted by Saint Mary's Hospital Research Ethics Board (SM-18-27, MP-18-20190500) in accordance with the Helsinki Declaration of 1975. Participants selected their preferred language (French or English) during enrollment with all subsequent data collected in their language of choice. Participants were compensated for completing self-report questionnaires at recruitment, in mid-late pregnancy, and 2 postpartum time points with a CAD $10 (a currency exchange rate of CAD $1=US $0.76 is applicable) e-gift card per time point.

Recruitment

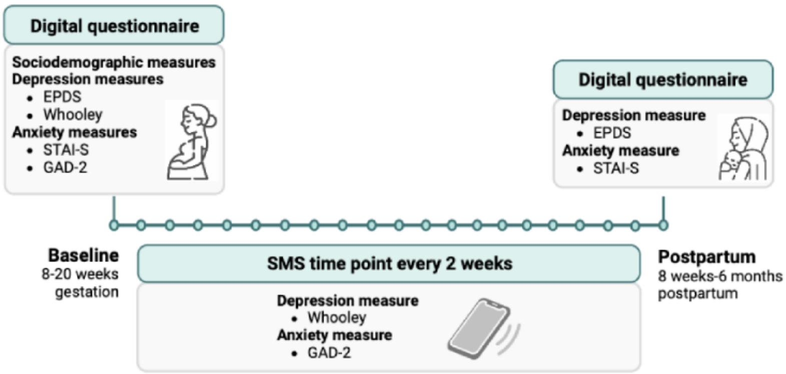
The Montreal Antenatal Well-Being Study (MAWS) is a cohort of 1130 pregnant participants recruited between August 2019 and March 2021. Participants were recruited from prenatal care clinics associated with 3 major birth centers in Montreal, Quebec (Saint-Mary's Hospital, Sainte-Justine Mother and Child University Hospital Center, and Lasalle Hospital). Following the onset of the COVID-19 pandemic, participants were also recruited through self-selection using targeted advertising on social media (Facebook). Eligibility criteria included being between 8 and 20 weeks of gestation; reading proficiency in French or English; aged 18 years or older; and owning a smartphone, tablet, or personal computer.

Measures

Sociodemographic Information

Sociodemographic data, including maternal age, race and ethnicity, immigration status, education level, income level, and history of mental health diagnosis were collected via self-report using a secure digital platform for data capture (REDCap [Research Electronic Data Capture]; Vanderbilt University) at baseline between 8 and 20 (mean 14.50, SD 3.80) weeks of gestation (Figure 1).

Figure 1. Data collection timeline of sociodemographic and mental health measures in the Montreal Antenatal Well-Being Study. EPDS: Edinburgh Postnatal Depression Scale; GAD-2: Generalized Anxiety Disorder 2-Item; STAI-S: State component of the State-Trait Anxiety Inventory.



Maternal Mental Health

Maternal depression and anxiety symptoms were assessed at baseline (recruitment) and at approximately 8 weeks postpartum (mean 8.73, SD 3.73 weeks) using validated clinical instruments through REDCap. Participants received a unique link via email at baseline and postpartum to complete their digital questionnaires on their own smartphones, tablets, or personal computers (Figure 1).

Maternal symptoms of depression were assessed using the Edinburgh Postnatal Depression Scale (EPDS). The EPDS is a widely used and validated 10-item self-report depression screening tool (Table S1 in Multimedia Appendix 1) with scores ranging from 0 to 30. EPDS sensitivity and specificity estimates range from 38% to 43% and 98% to 99%, respectively [61]. Maternal symptoms of anxiety were assessed using the State component of the State-Trait Anxiety Inventory (STAI-S). The STAI-S scale is a 20-item, self-report scale commonly used to measure an individual's anxiety symptoms at the time of assessment (Table S1 in Multimedia Appendix 1). Each item is measured on a 4-point Likert scale. Higher scores indicate greater state anxiety symptoms. Internal consistency coefficients for the scale have ranged from 0.86 to 0.95; test-retest reliability coefficients have ranged from 0.65 to 0.75 [62]. Depression and anxiety symptoms of clinical concern are defined as scores 13 on the EPDS and 40 on the STAI-S, respectively (Table S1 in Multimedia Appendix 1).

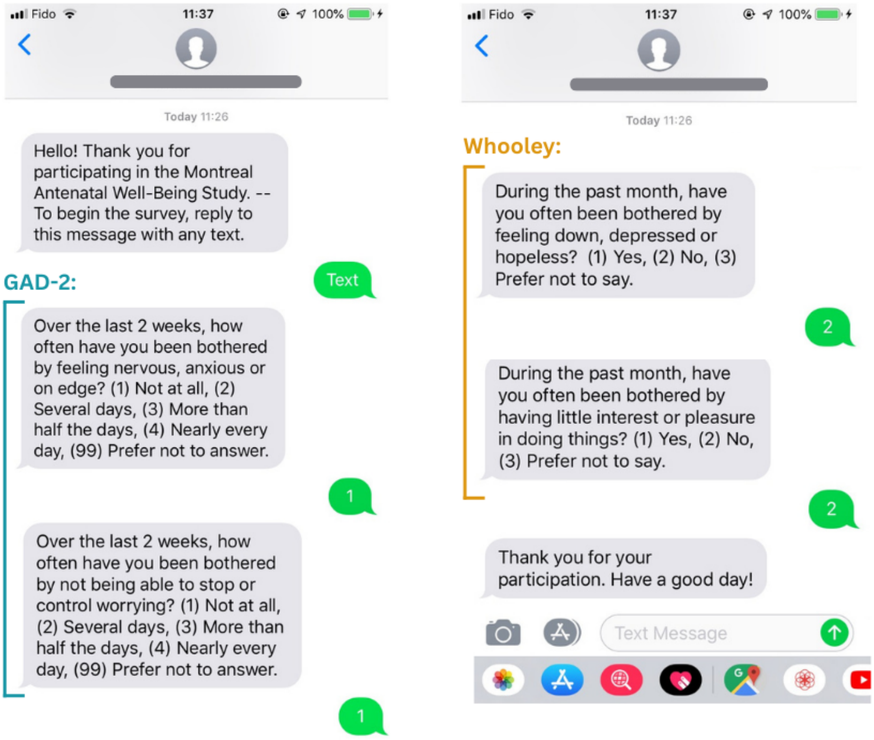
Text Message–Based Screening Protocol

Text message–based screening was performed using REDCap-Twilio integration (Figure 2 and Table S2 in Multimedia Appendix 1). Participants received their first text message time point 14 days after enrollment and then at 14-day intervals until the participant reached 8 weeks postpartum. If the survey was not initiated after the first text message, participants were prompted with a reminder text message sent 24 hours and then 48 hours after the initial text message. If participants failed to respond to 5 consecutive text message time points, no further messages were sent. A text message time point screening assessment consisted of 4 questions sent via separate text messages, which assessed symptoms of depression (Whooley Questions) [63] and anxiety (Generalized Anxiety Disorder 2-Item [GAD-2] questionnaire) [64], using 2 questions for each construct.

The Whooley Questions probe symptoms of depressed mood and anhedonia (Table S1 in Multimedia Appendix 1) and are used for routine screening of maternal depression in many countries including the United Kingdom [27]. Participants who respond "yes" to at least 1 of the 2 questions (score 1) may benefit from further evaluation (~95% sensitivity) [63]. Conversely, a negative screen suggests that no further evaluation is required. The Whooley Questions have a higher sensitivity compared to similar brief screening questionnaires for depression symptoms such as the 2-item Patient Health Questionnaire [65,66]. The GAD-2 assesses symptoms of anxiety and worry (Table S1 in Multimedia Appendix 1). Responses are scored using a Likert scale ranging from 0 to 3. An instrument score 3 has an 86% sensitivity and 83% specificity for identifying possible cases of generalized anxiety disorder and may warrant further evaluation by a clinician [64]. These 2 brief questionnaires were selected based on their suitability for delivery via text message and based on their existing use as part of universal perinatal mental health screening in the United Kingdom [27].

For this analysis, we included all maternal participants in the MAWS cohort who had received at least 1 text message time point, that is, one set of both depression and anxiety screening questions via text message. We excluded those who had withdrawn from the study prior to 8 weeks postpartum (n=60) and MAWS participants who did not receive a single text message because their area code was not covered by our service provider (n=23). This gave rise to a sample size of 1047, including 933 (89.1%) participants who responded to at least 1 text message time point and 114 (10.9%) participants who did not respond to any text message time points.

Figure 2. Text messages sent to Montreal Antenatal Well-Being Study participants' personal smartphones at 14-day intervals from enrollment in the study until 8 weeks postpartum. GAD-2: Generalized Anxiety Disorder 2-Item.



Hello! Thank you for participating in the Montreal Antenatal Well-Being Study. -- To begin the survey, reply to this message with any text.

Text

Over the last 2 weeks, how often have you been bothered by feeling nervous, anxious or on edge? (1) Not at all, (2) Several days, (3) More than half the days, (4) Nearly every day, (99) Prefer not to answer.

1

Over the last 2 weeks, how often have you been bothered by not being able to stop or control worrying? (1) Not at all, (2) Several days, (3) More than half the days, (4) Nearly every day, (99) Prefer not to answer.

1

During the past month, have you often been bothered by feeling down, depressed or hopeless? (1) Yes, (2) No, (3) Prefer not to say.

2

During the past month, have you often been bothered by having little interest or pleasure in doing things? (1) Yes, (2) No, (3) Prefer not to say.

2

Thank you for your participation. Have a good day!

Statistical Analyses

We defined "respondents" as participants who responded to at least 1 text message time point (n=933). "Nonrespondents" were defined as participants who did not respond to any text message time points (n=114). Fisher tests with Monte-Carlo simulations (categorical variables) and 2-tailed *t* tests (continuous variables) were used to investigate if any sociodemographic or mental health measures collected at baseline and postpartum significantly differed between respondents and nonrespondents.

In addition, hurdle regression models using a log link function were used to determine associations between participants' total number of text message time points completed and participants' sociodemographic variables or mental health, adjusting for the number of text message time points each participant received. Hurdle models considered the number of text message time points completed by participants according to its two possible outcomes: (1) zero time points completed, the outcome of nonrespondents (zero model); and (2) a positive number of time points completed, the outcome of respondents (count model) [67,68]. Binomial logistic regression with a log link was used for the nonrespondent zero model. On the other side of the "hurdle," a zero-truncated Poisson distribution was used for the respondent count model. For categorical sociodemographic variables, the relative difference between the data fitting a null model containing no predictor variables and a model containing each of the sociodemographic variables individually was tested with a likelihood ratio test. For continuous baseline mental health measures, Exp (β), or the exponential value of the unstandardized coefficient β (e^{β}), provided the incidence risk ratio for the count model, that is, the predicted ratio of the number of text message time points completed per unit increase in the predictor variables, whereas Exp (β) in the zero model provided the odds ratio. Adjusted hurdle models considered predictors of interest together with relevant covariates including self-reported race and ethnicity, income level, and education level.

Correlations (Spearman for ordinal and Pearson for continuous variables) were computed to determine the association of sociodemographic or mental health variables collected at baseline with participants' "response rate," which was defined as the number of text message time points they responded to divided by the number of text message time points they received. Thus, analyses of participant response rate account for variation in gestational age at recruitment, which determined the total number of possible text message screening time points.

Finally, linear regression models were used to determine if measures of anxiety or depression from brief text message screening assessments helped to better predict postpartum depression and anxiety symptoms than assessments of mental health at baseline. Participant response rate was also considered in these models to test whether participant compliance was a better predictor of mental health outcomes than symptom data. The Akaike Information Criterion was used as a measure of model fit to determine which of a set of predictors (ie, response rate, baseline mental health scores, or scores from the brief text message–based mental health screening questions) were the best predictors of elevated scores on validated clinical measures of postpartum depression and anxiety (EPDS and STAI-S). All analyses were run using R statistical software (version 4.2.2; R Foundation for Statistical Computing). The *pscl* package was used for the hurdle regression analyses.

Results

Overview

Over the course of the study, participants received an average of 14 (SD 4.66) text message screening assessments (text message time points) and responded to approximately 11 (SD 6.31) of these assessments. Some participants (n=40) received only the first 2 text message time points due to a REDCap configuration error. These participants were retained, and analyses account for the total number of text message time points received. Tables S3 and S4 in Multimedia Appendix 1 present the number of text message time points sent and answered by participants at each time point, and Table 1 shows the participant text message response rate per time point. Summary statistics of the text message time points sent and answered at each gestational or postpartum week (based on reported week of gestation at study entry) are included in Table S5 in Multimedia Appendix 1.

Participation in a Text Message–Based Screening Protocol

Sociodemographic Characteristics of Respondents and Nonrespondents

Participants who responded to at least 1 text message screening assessment (ie, respondents) differed from nonrespondents on several sociodemographic factors (Table 2). Fisher tests indicated that, compared to the nonrespondent group, the respondent group was comprised of more individuals who identified as White (587/907, 64.7% vs 39/96, 40.6%; *P*<.001), who were Canadian citizens (603/768, 78.5% vs 41/77, 53.2%; *P*<.001), and who spoke 2 (483/917, 52.7% vs 46/98, 46.9%; *P*=.01) or more languages (286/917, 31.2% vs 24/98, 24.5%; *P*=.01), mainly French and English (425/566, 75.1% vs 29/53, 54.7%; *P*=.004). Respondents reported higher educational attainment (postgraduate: 268/909, 29.5% vs 15/94, 16%; *P*=.005) and higher household income (CAD $150,000 or more: 176/832, 21.2% vs 10/84, 11.9%; *P*<.001) than nonrespondents (Table 2). At baseline, respondents were more likely than nonrespondents to be primiparous (never given birth: 399/827, 48.3% vs 34/83, 41%; *P*=.049; Table 2).

Table 2. Baseline sociodemographic characteristics of respondents and nonrespondents.

	Full sample (n=1047)	Nonrespondents (n=114, 10.9%)	Respondents (n=933, 89.1%)	Fisher test *P* value

Baseline and Postpartum Mental Health of Respondents and Nonrespondents

Respondents and nonrespondents reported similar levels of depression and anxiety symptoms both at baseline and postpartum (Table 3; see also Table S6 in Multimedia Appendix 1). The number of individuals who reported having received a mental health diagnosis was not significantly different between groups (*P*=.15; Table 2).

Table 3. Mental health measure scores of respondents and nonrespondents.

[c] STAI-S: State component of the State-Trait Anxiety Inventory (scores were prorated if ≥80% data available).

Predictors of the Number of Text Message Screening Time Points Completed

Next, we asked which factors predicted the total number of responses to regular (every 2 weeks) text message screening assessments across pregnancy (see Table S7 in Multimedia Appendix 1 for bivariate correlations). Unadjusted bivariate hurdle models indicated that there were significant differences in the number of text message time points completed based on self-reported race and ethnicity (*P*<.001), immigration status (*P*<.001), number of languages spoken fluently (*P*=.002), French-English bilingualism (*P*<.001), education level (*P*<.001), household income level (*P*<.001), relationship status (*P*<.001), and number of previous births (*P*=.01; Table 4), with self-reported race and ethnicity having the strongest effect. Table 4 also describes the results from the adjusted hurdle model where maternal race and ethnicity (*P*<.001), education (*P*=.001), household income (*P*=.02), and relationship status (*P*=.03) remained significantly and independently associated with the total number of text message time points completed by participants. Maternal age at baseline was not significantly associated with the likelihood of responding to one (or more) text message time points after considering relevant covariates (Table S8 in Multimedia Appendix 1).

Measures of maternal mental health at baseline also predicted the total number of text message time points completed across the duration of the study (Table 5 and Table S9 in Multimedia Appendix 1). A 1-point increase in EPDS and STAI-S scores at baseline was associated with a respective decrease of 1% (e^{β}=0.99) and 0.3% (e^{β}=0.997) in the average number of text message time points answered by participants (Table 5). Thus, for each SD increase in maternal depression or anxiety scores, the average number of text message time points completed was

4.7% and 3.3% lower, respectively. In hurdle models adjusted for self-reported race and ethnicity, education level, and household income level, baseline EPDS (*P*<.001) and STAI-S scores (*P*=.03) remained significant predictors of the total number of text message-based screening assessments completed (Table 5). In contrast, a previous mental health diagnosis (reported at baseline) did not improve the prediction of number of text message time points completed by participants in both the unadjusted (*P*=.17) and adjusted (*P*=.91) models (Table 4).

Table 4. Associations between baseline categorical sociodemographic variables and participants' number of text message time points completed.

[a] Exp (β), or the exponential value of β (e^{β}), provides the incidence risk ratio for the count model, that is, the association between baseline mental health measure scores and the incidence rate of participants responding to a positive number of text message time points.

[b] Exp (β) provides the odds ratio in the zero model, that is, the association between baseline mental health measure scores and the odds of responding to at least 1 text message time point.

[c] EPDS: Edinburgh Postnatal Depression Scale.

[d] Values in italics format indicate statistical significance.

[e] STAI-S: State component of the State-Trait Anxiety Inventory.

[f] Adjusted hurdle regression models include ethnicity, income level, and education level as covariates.

Text Message Response Rate Does Not Outperform Brief Symptom Measures in the Prediction of Postpartum Anxiety and Depression Symptoms

Given the associations we observed between baseline measures of maternal mental health and the number of text message time points participants responded to, we next asked if participant text message response rate was a better predictor of postpartum mental health than symptom data from brief screening tools. Specifically, these models tested if text message response rate was a better predictor of depression and anxiety symptoms (measured by EPDS and STAI-S) at approximately 8 weeks postpartum than scores derived from the Whooley and GAD-2 questionnaires. Text message response rate did not improve the prediction of postpartum depression or anxiety (Table S10 in Multimedia Appendix 1). Similar results were found in the adjusted models, suggesting that measures of selection bias (as reflected by text message response rate) were not a significant predictor of postpartum depression or anxiety symptoms (Table S10 in Multimedia Appendix 1). In contrast, we found that participant GAD-2 scores collected via text message proximal (average 7.3, SD 21.7 days) to the postpartum screening assessment provided the strongest prediction of maternal postpartum depression and anxiety symptom levels (Table 6).

Table 6. Comparison of predictors (based on model fit statistics) of postpartum depression and anxiety symptoms. Model fit was estimated using the Akaike information criterion (AIC) with lower values indicating a better fit or prediction.

Outcome	Predictor						
	Response rate	Baseline measures		Last gestation measures		Last postpartum measures	
		STAI-S[a] score	EPDS[b] score	GAD-2[c] score	Whooley score	GAD-2 score	Whooley score
EPDS score—postpartum	3959.3	3832.5	3829.27	3893.5	3917.27	*3722.56* [d]	3813.89
STAI-S score—postpartum	5063.27	4896.73	4963.46	4985.09	5002.80	*4840.15*	4920.96

Discussion

Principal Findings

This study provides a comprehensive analysis of sociodemographic and mental health selection bias in participation in a text message–based perinatal mental health screening protocol. Overall, we found some evidence of selection bias that was patterned by maternal characteristics including race and ethnicity, income level, education, and parity. While we did not find strong evidence for an impact of maternal mental health on initial participation in our text message–based screening protocol, we did observe fewer total text message time points completed based on baseline maternal depression and anxiety symptoms. These findings suggest that text messaging may be a useful tool in the context of perinatal mental health screening. However, this study highlights important individual-level factors that may impact the effectiveness of text message–based mental health screening.

Sociodemographic and Mental Health Factors Predict Participation in Text Message–Based Screening

This study identified several sociodemographic variables that were associated with initial participation in a text message–based mental health screening protocol, and several of these factors also influenced the total number of text message time points completed over time. Specifically, respondents were more likely to identify as White, report Canadian citizenship, speak more languages (predominantly French-English bilingualism), have higher educational attainment, have higher income, and have fewer children. Self-reported race and ethnicity, education level, household income level, and relationship status were also associated with the number of text message time points answered by respondents. Our findings are consistent with previous studies, which have identified higher engagement with mobile-based health interventions among socially advantaged groups, reflecting potential challenges faced among disadvantaged groups, such as time constraints, differences in communication needs and preferences, and varying levels of literacy, trust, and comfort with digital technology [69,70]. Previous studies demonstrating the feasibility of text message– or mobile-based perinatal mental health screening have generally been performed in well-educated, higher-income cohorts [52] or in smaller cohorts than this study [71]. For example, a previous Canadian study focused predominantly on women with a university degree (865/937, 92%), which contrasts with this study (665/1003, 66% college-educated). Further empirical and qualitative studies are needed to parse the role of these factors and their interplay in the prediction of participation in text message–based screening. This work should include racially, culturally, and economically diverse samples and ideally incorporate qualitative studies to better understand individual-level factors that may act as barriers to participation in a text message–based screening of perinatal mental health.

Maternal depression and anxiety symptoms as well as previous mental health diagnoses were comparable across respondents and nonrespondents at baseline and postpartum. Thus, the likelihood of participation in a text message–based mental health screening protocol does not appear to vary as a function of maternal mental health. This finding provides supportive evidence of the utility of this approach to assess mental health symptoms in pregnant individuals. However, we did observe a significant negative association between maternal symptoms of depression and anxiety at baseline and the total number of text message time points answered over time. Our finding is consistent with a UK-based study that found that a history of depression and a history of use of psychiatric medication were negatively associated with the use of a postnatal depression screening app [71]. Similarly, a Japanese perinatal cohort reported that maternal psychological distress during pregnancy correlated with nonresponsiveness to follow-up questionnaires in the postpartum period [72]. Collectively, these findings suggest that the burden of repeated mental health assessments may lead to increased attrition among vulnerable groups. Thus, the frequency of mental health screening assessments is an important consideration for public health initiatives that seek to repeatedly assess maternal mental health across the perinatal period.

Response Rate and Brief Screening Scores as Predictors of Postpartum Depression and Anxiety Symptoms

Anxiety symptoms, as reported using the GAD-2 questionnaire sent via text message, emerged as the strongest predictor of postpartum symptoms, while participants' text message response rate was not significantly associated with postpartum mental health symptoms. Specifically, the GAD-2 score most proximal to the postpartum assessment of depression and anxiety, with an average interval of 7.3 days between these assessments, was the best predictor of postpartum symptom levels. This finding is unsurprising as closely spaced assessments of similar constructs are likely to be highly intercorrelated. However, we did note a stronger prediction of both postpartum depression and anxiety symptoms by GAD-2 scores than scores derived from the Whooley Questions, which assess symptoms of depression. This finding is consistent with a previous report highlighting a robust association between prenatal anxiety and postpartum depression [73]. Our multivariable analyses show that the GAD-2 is a helpful brief screening tool that captures additional variance in postpartum anxiety and depression symptoms (beyond that explained by sociodemographic factors) [64,74].

Overall, the adoption of digital, mobile-based short-form perinatal mental health screening has the potential to address clinical barriers such as time and resource constraints. Consistent with previous findings, the high rate of participation from the MAWS sample in the text message screening protocol (933/1047, 89.1%) also suggests that text message–based screening may be appealing to a broad section of pregnant and postpartum individuals [52-54]. Our findings emphasize the need to identify and remove the barriers that contribute to lower patient engagement in digital screening protocols among disadvantaged groups who are at higher risk of developing a perinatal mental health disorder [75]. Such barriers could include time constraints, reduced access to a mobile device, language barriers, mistrust of health institutions, and stigma associated with mental health, among others. Overcoming these barriers may help more fully realize the clear potential of text messaging technology to reduce inequitable access to perinatal mental health care.

Limitations

This study is not without limitations. First, this study only included participants who owned a smartphone, tablet, or personal computer, and due to the COVID-19 pandemic, 216 (20.6%) of the 1047 MAWS cohort sample participants were recruited using targeted advertisements on social media. Thus, the participation rate in our text message–based screening protocol (933/1047, 89.1%) may be higher than studies that focus on a more general perinatal population. However, we note that only 1 (0.03%) of 3761 individuals approached to participate in MAWS did not own a smartphone, tablet, or personal computer. Likewise, our participation rate was similar to Lawson et al [52] (930/937, 99%), who carried out a text message–based screening protocol in a postpartum cohort.

Second, although studies have previously demonstrated the high accuracy and internal consistency of existing clinical screening tools like those administered to MAWS participants (Whooley, GAD-2, EPDS, and STAI-S) across ethnically diverse populations [76-80], many of these instruments contain idioms that may not translate well to different languages and may lack sensitivity in the conceptualization of symptoms of perinatal maternal depression and anxiety across different cultures. Future studies would benefit from considering culturally relevant research methodologies and questionnaires for digital screening of perinatal mental health [32].

These limitations notwithstanding, a major strength of the study design is that it allowed us to collect longitudinal data on participants who did not participate in the text message component of the study. Studies whose sole focus is on testing the feasibility of a text message–based screening protocol are, by nature of their design, unable to collect longitudinal data on nonengaged participants. Our findings therefore bring much-needed insights into the sociodemographic and mental health profile of pregnant individuals who choose to participate in and consistently respond to text message–based mental health screening assessments.

Conclusions

New approaches are required to better identify and treat perinatal mood and anxiety disorders, which cause profound human distress and result in large economic costs. Our study provides preliminary support for the feasibility and utility of a text message–based perinatal mental health screening protocol; the first evidence of this kind derived from a bilingual Canadian cohort. However, our findings also highlight how digital technologies could contribute to further disparities in mental health screening and treatment, an equity issue that should be a central focus for health policy formation.

Acknowledgments

The authors would like to extend their utmost gratitude to the pregnant participants who gave their time so generously to make this study possible. This work is also made possible by the generous support of the Canada First Research Excellence Fund: Healthy Brains for Healthy Lives (Discovery Grant and Innovative Ideas Award—KJOD), the Chamandy Foundation (Program Award—TVN and KJOD), the Ludmer Centre for Neuroinformatics and Mental Health—KJOD, the Canadian Institute for Advanced Research (CIFAR Child and Brain Development Program Fellowship—KJOD), the Brain and Behavior Research Foundation (NARSAD Young Investigator Grant—KJOD), Ferring Pharmaceuticals (COVID-19 Investigational Grant in Reproductive Medicine and Maternal Health—TVN), the Fonds de Recherche Québec Santé (FRQS Chercheur Boursier Jr 1 309805—TCM), and the Quebec Population Health Research Network (RRSPQ Support for Scientific Publication Grant—TCM).The study team would like to thank Dr Michael Meaney and his group for providing access to digital infrastructure used as part of this study.

Authors' Contributions

JB drafted the paper and contributed to the interpretation of the data. CHR, KPD, CG, and JB conducted the literature review. CHR and KPD contributed to the drafting and critical revisions of the paper. GE and HP conducted the data analysis and contributed to the interpretation of the data. KJOD, TCM, and TVN contributed to the study's conception and design. KJOD and TCM contributed to the interpretation of the data and critical revisions of the paper. All authors have read and approved the final version of the manuscript.

Abstract

Background: Mental disorders are the leading cause of disease burden among youth. Effective prevention of mental disorders during adolescence is a critical public health strategy to reduce both individual and societal harms. Schools are an important setting for prevention; however, existing universal school-based mental health interventions have shown null, and occasionally iatrogenic, effects in preventing symptoms of common disorders, such as depression and anxiety.

Objective: This study aims to report the adaptation process of an established, universal, school-based prevention program for depression and anxiety, OurFutures Mental Health. Using a 4-stage process; triangulating quantitative, qualitative, and evidence syntheses; and centering the voices of young people, the revised program is trauma-informed; lesbian, gay, bisexual, transgender, nonbinary, queer, questioning, and otherwise gender and sexuality diverse (LGBTQA+) affirmative; relevant to contemporary youth; and designed to tailor intervention dosage to those who need it most (proportionate universalism).

Methods: Program adaptation occurred from April 2022 to July 2023 and involved 4 stages. Stage 1 comprised mixed methods analysis of student evaluation data (n=762; mean age 13.5, SD 0.62 y), collected immediately after delivering the OurFutures Mental Health program in a previous trial. Stage 2 consisted of 3 focus groups with high school students (n=39); regular meetings with a purpose-built, 8-member LGBTQA+ youth advisory committee; and 2 individual semistructured, in-depth interviews with LGBTQA+ young people via Zoom (Zoom Video Communications) or WhatsApp (Meta) text message. Stage 3 involved a clinical psychologist providing an in-depth review of all program materials with the view of enhancing readability, improving utility, and normalizing emotions while retaining key cognitive behavioral therapy elements. Finally, stage 4 involved fortnightly consultations among researchers and clinicians on the intervention adaptation, drawing on the latest evidence from existing literature in school-based prevention interventions, trauma-informed practice, and adolescent mental health.

Results: Drawing on feedback from youth, clinical psychologists, and expert youth mental health researchers, sourced from stages 1 to 4, a series of adaptations were made to the storylines, characters, and delivery of therapeutic content contained in the weekly manualized program content, classroom activities, and weekly student and teacher lesson summaries.

Conclusions: The updated OurFutures Mental Health program is a trauma-informed, LBGTQA+ affirmative program aligned with the principles of proportionate universalism. The program adaptation responds to recent mixed findings on universal school-based mental health prevention programs, which include null, small beneficial, and small iatrogenic effects. The efficacy of the refined OurFutures Mental Health program is currently being tested through a cluster randomized controlled trial with up to 1400 students in 14 schools across Australia. It is hoped that the refined program will advance the current stalemate in universal school-based prevention of common mental disorders and ultimately improve the mental health and well-being of young people in schools.

Introduction

Background

Mental disorders, such as depression and anxiety, are the leading causes of disease burden among youth [1]. Almost two-thirds of those who experience a mental disorder are first diagnosed before the age of 25 years [2,3]. Global evidence suggests depressive and anxiety symptoms have been increasing among adolescents since the 1980s [4-7]. This was further compounded by the COVID-19 pandemic, culminating in a current crisis characterized by doubled prepandemic rates of depression and anxiety among youth and increased attempts at suicide [8,9]. These trends highlight the urgency of prioritizing efforts to address mental ill-health.

Alarmingly, many people experiencing mental health disorders do not receive the care they need. In high-income countries, it is estimated that only 33% of people with depression access treatment, while in low-income countries, just 8% of those in need access treatment [10]. Services are overburdened, with high out-of-pocket costs, lengthy wait times, and other barriers prohibiting access to treatment for our youth [11]. While improving access to ensure treatment coverage for those who need it is critical, greater attention and resources must also be directed to *preventing* these disorders.

Schools are an ideal setting for implementing mental health prevention programs [12], enabling broad reach before the peak age of onset of mental disorders (14.5 years [2]). Universal delivery of mental health programs is typically low cost and practical for schools, enables tailoring of programs to students' developmental level, facilitates scalability, and is nonstigmatizing [13,14]. However, meta-analyses and recent large-scale randomized controlled trials (RCTs) of universal school-based depression and anxiety prevention programs show mixed results, including null effects, small benefits on symptom reduction in the short term, and even potential iatrogenic effects, particularly for individuals with preexisting mental health symptoms [15-20]. Indeed, the consistent observation of small, null, and iatrogenic effects of universal school-based mental health prevention activities has garnered significant global attention [21-23], with several editorials calling for a shift in universal approaches for school-based prevention for depression [21,23].

Therefore, despite the promise of school-based, universal mental health prevention, existing evidence demonstrates a clear need to improve these interventions or rethink the approach used in universal school-based prevention. One solution that has been proposed is the use of targeted prevention approaches, which selectively target subgroups within the population that have been identified as being at an elevated risk for mental ill-health [12]. Meta-analytic estimates of targeted school-based depression and anxiety prevention programs consistently show larger effect sizes compared with universal programs [16,17]. However, targeted programs often incur greater implementation and resource burden, requiring sound identification and communication of individual risk, both in terms of sensitivity and specificity in allocating individuals to receive an intervention or not, as well as care to avoid labeling or causing stigma through this process [24].

One potential path forward that leverages the strengths of both universal and selective prevention is "proportionate universalism." This is the notion that universal public health policies or interventions be designed to proportionately (equitably) benefit those who need it the most [25,26]. A growing body of public health and health policy literature suggests that this is a pragmatic step toward achieving optimal global health by harnessing universal delivery but tailoring intervention dosage and content based on need [25]. By applying proportionate universalism to mental health prevention, those exhibiting elevated mental health symptomatology would receive or could opt in to receive additional intervention components, such as psychoeducation, skills training, and evidence–based early intervention resources. This has the potential to address a notable challenge in universal mental health prevention, whereby the same intervention is delivered to individuals with varying levels of preexisting symptoms and risk. For those with low symptoms or levels of risk, universal intervention may lack relevance and perceived usefulness, limiting engagement, while for those with preexisting symptoms, its low-intensity therapeutic content may raise awareness or discomfort of unpleasant thoughts and emotions but could be insufficient in helping these individuals manage their distress [20,27]. Providing flexibility in the dosage of the intervention, where individuals can choose to receive additional skills training or psychoeducation, could improve the relevancy of prevention SMS text messaging across the spectrum of preexisting symptomatology. Moreover, giving individuals a choice as to which intervention components they receive could improve adherence, retention, and ultimately, effectiveness [28]. In practice, however, literature is scant on real-life applications of this paradigm.

Another noticeable limitation of universal mental health prevention programs is a lack of attention to the social factors contributing to mental health difficulties. A wealth of literature has identified the elevated risk of mental health difficulties among young people exposed to trauma or adversity, such as child abuse, neglect, or exposure to domestic violence. Given that, up to 62% of Australians have experienced maltreatment or domestic violence during childhood and adolescence [29], programs aiming to address or prevent adolescent mental health problems must be trauma-informed. In addition, growing research has highlighted the disproportionate rates of mental ill-health among lesbian, gay, bisexual, transgender, nonbinary, queer, questioning, and otherwise gender and sexuality diverse (LGBTQA+) young people [30,31]. Nearly half of young LGBTQA+ Australians have ever received a diagnosis of generalized anxiety disorder and depression [32]. Transgender people and gender diverse people (binary and nonbinary; henceforth, "trans") are people with a gender identity different from the one presumed for them at birth. Relative to their sexuality diverse peers, transgender young people report even higher rates of generalized anxiety disorder and depression conditions [32]. Mental ill-health disparities affecting LGBTQA+ young people widen through adolescence [33]. LGBTQA+ young people experience daily, chronic discrimination based on their genders and sexualities and, moreover, are more likely than their cisgender, heterosexual peers to report nonidentity–related traumatic events, such as intimate partner abuse and sexual assault [34]. Notably, it is those experiences of daily, chronic discrimination and inability to feel safe that bear more mental health consequences than traumatic events [34]. Moreover, the mental health effects of both minority stressors and nonidentity–specific traumatic events are disproportionately shouldered by transgender young people [34]. Although schools can be affirming and supportive of LGBTQA+ young people [35], high rates of school-based bullying, harassment, exclusion, and isolation continue to be documented among contemporary LGBTQA+ young people [36]. Significant variability in school and staff-level preparedness to support underscores a dire need for additional school-wide LGBTQA+ affirmative initiatives [30]. Henceforth, to effectively respond to either the needs of young people exposed to trauma or adversity or LGBTQA+ young people necessitates an integrated approach, reflecting how young people undergo dynamic, interrelated experiences of trauma, adversity, gender, and sexuality. Therefore, a trauma-informed, LGBTQA+ affirmative approach that applies proportionate universalism may be effective in preventing and reducing the escalation of mental health symptoms among adolescents, particularly adolescents exposed to trauma or adversity and LGBTQA+ adolescents.

One universal, school-based OurFutures Mental Health program (formerly Climate Schools Mental Health) has similarly shown mixed effects for preventing anxiety and depression [37]. It was developed in 2009 as a web-based cognitive behavioral therapy (CBT)–based mental health education program. The content was delivered over six 30-minute lessons (including a 10-minute weekly revision) comprising skill acquisition; psychoeducation; and management of thoughts, emotions, and behaviors specific to depression and anxiety [38]. A feasibility trial demonstrated improvements in well-being and knowledge about stress and reductions in measures of distress [38]. The program was subsequently divided into 2 programs targeting depression and anxiety separately and was tested in a 3-arm, cluster RCT with 976 year 9 and 10 students from 12 Australian schools. Compared with health education as usual, the anxiety intervention resulted in significant reductions in anxiety symptoms, and the depression intervention reduced both anxiety and depressive symptoms [39].

In 2013, the depression and anxiety modules were amalgamated and condensed into six 40-minute lessons to create the Climate Schools Mental Health program to reduce content overlap and decrease time demands for schools [40]. Lessons included a 20-minute cartoon storyline, followed by optional teacher–delivered activities involving CBT–based skills practice. Teachers and students were also provided with downloadable lesson summaries to reinforce the content delivered in the lessons. The program was developed through input from an experienced clinical psychologist; focus groups with approximately 30 students from 2 independent schools in Sydney, Australia; and consultation with numerous health and educational professionals to verify the program's clinical and educational validity [40]. Between 2013 and 2016, a cluster RCT of >6000 students of grades 8 and 9 (aged approximately 13-15 years) investigated the effectiveness of 3 interventions, including Climate Schools Mental Health, Climate Schools Substance Use, and both Climate Schools Mental Health and Climate Schools Substance Use programs combined, for preventing depression, anxiety, and substance use, accordingly, compared with an active control (health education as usual). Additional detail regarding the components of Climate Schools Substance Use is published elsewhere [41]. Over a 30-month period, students in the combined group experienced increased knowledge of alcohol, cannabis, and mental health and decreased growth in anxiety symptoms [42]. However, further post hoc analyses revealed the students in the stand-alone Climate Schools Mental Health condition improved their knowledge of mental health but reported no improvement in other mental health outcomes compared with the control condition [37]. Moreover, the participants in the stand-alone mental health group also reported transient increased internalizing scores at the 6-month and 12-month postintervention time points compared with controls; however, these were not sustained at further follow-ups [37].

Objectives

In light of previous findings from RCTs of the OurFutures Mental Health program, as well as existing evidence from other universal school-based mental health prevention approaches, the OurFutures Mental Health program was refined from 2022 to 2023. This paper describes this refining process. We aimed to explore and understand young peoples' perceptions and experiences of the OurFutures Mental Health program within previous trials, source input from young people to refine the program to be trauma-informed and gender and sexuality inclusive, and incorporate the principles of proportionate universalism.

Methods

Overview

Program adaptation occurred from April 2022 to July 2023, using a four-stage approach: (1) analysis of evaluation data from the original Climate Schools Mental Health program; (2) focus groups and interviews conducted with young people, including LGBTQA+ youth; (3) content review by a clinical psychologist; and (4) expert team consultation and literature review.

This paper adheres to guidance for reporting intervention development studies in health research (Guidance for the Reporting of Intervention Development) [43].

Ethical Considerations

Ethics approval was granted by the University of Sydney Human Research Ethics Committee (2022/664) and for Stage 1 from the University of New South Wales Human Research Ethics Committee (HC13073). All participants provided written informed consent. In stage 1, participants were entered into a prize draw to win an iPad. In stage 2, focus group participants were entered into a prize draw to win an Aus $100 (US $65.84) gift card, and interview participants were reimbursed with an Aus $20 (US $13.17) gift card.

Stage 1: Analysis of Evaluation Data From the Original Climate Schools Mental Health Program

Between June 2022 and February 2023, we conducted a mixed methods analysis of student evaluation data (n=762, mean age 13.5, SD 0.62 y) collected immediately after the delivery of the Climate Schools Mental Health program (2015) in a previous trial. The full methodology of the trial is published elsewhere [42,44]. Students responded to seven 5-point Likert scale items regarding how strongly they agreed or disagreed with statements regarding satisfaction, relevance, and helpfulness of the program. Two open-ended items also asked students to identify “one good thing” and “one bad thing” about the program. Open-ended items were analyzed using a 6-step thematic analysis approach [45]. Differences in responses by sex and baseline mental ill-health symptoms (Generalized Anxiety Disorder questionnaire [46], Patient Health Questionnaire-9 [47], and Emotional Symptoms subscale of the Strengths and Difficulties Questionnaire [48]) were also tested using multivariate logistic regression models, which controlled for binary sex. Full information on the evaluation has been published elsewhere [27].

Stage 2: Focus Groups and Interviews Conducted With Young People, Including LGBTQA+ Youth

Overview

The adaptation involved extensive consultation with young people, including LGBTQA+ young people. Duty of care procedures were created, including having a clinical psychologist on standby, although these procedures were not required during the consultations. Specifically, this consultation process comprised 3 stages.

Stage 2.1: School-Based Focus Groups (General Population of Adolescents)

To seek input on current sources of stress experienced by young people, as well as feedback on the OurFutures Mental Health storylines, focus groups were conducted in 2 Australian high schools. Given that 1 school had a large student cohort, 2 separate focus groups were conducted within the school, resulting in 3 focus groups across 2 schools (n=39). It was determined that this is an appropriate number for data saturation [49,50].

Independent secondary schools in Sydney, Australia, were contacted in mid-2022 using publicly available email addresses and phone numbers and invited to participate in focus groups. Two schools agreed to participate and sent information and consent forms to parents of their grade 8 students (aged approximately 13-14 years). Students were required to sign their own information and consent form.

Focus groups were each cofacilitated by 2 researchers each and took place in November 2022 and February 2023. A semistructured focus group guide was used, comprising 12 questions (Multimedia Appendix 1) centered on major stressors, how they affect mental health, and strategies youth use to cope. Students were also shown scenes from the existing program, and facilitators sought specific feedback regarding the characters, storylines, and language. This set of discussion questions permitted flexibility for participants to expand on their responses and explore themes in greater depth.

School staff were not present in the room during the focus groups. Focus groups were audio-recorded and later transcribed using transcription software Otter (Otter.ai, Inc). Focus groups lasted for approximately 40 minutes, and participants could opt in to enter a draw to receive an Aus $100 (US $65.84) gift voucher (1 per school).

Stage 2.2: Consultations With an LGBTQA+ Youth Advisory Committee

An LGBTQA+ youth advisory committee (YAC) was established, comprising 8 LGBTQA+ young people aged 17 to 19 years across rural or regional and metropolitan areas in New South Wales, Australia. There was a diverse representation of gender and sexuality in the YAC membership. YAC members were recruited through advertisements shared through professional networks, including newsletters and social media channels. Targeted advertisements were further shared through collaborative efforts from local LGBTQA+ youth health organizations. LGBTQA+ YAC members were reimbursed with Aus $30 (US $19.75) gift vouchers for each meeting they attended. Over the course of intervention adaptation, the YAC met 3 times: August 2022, November 2022, and March 2023. Chaired by SB, these early meetings focused on high-level discussions about the process and ethics of adapting universal programs intended to reach all young people, to be simultaneously affirming, inclusive, and supportive of LGBTQA+ young people. In the interest of maintaining comfortable, confidential spaces, these meetings were not recorded; however, detailed independent field notes were taken by SB and RT for later comparison and review. Iterative discussion based on these field notes generated guiding principles and accompanying recommendations stemming from LGBTQA+ YAC discussions for the adaptation of OurFutures Mental Health to be LGBTQA+ affirming and inclusive.

Stage 2.3: Interviews With LGBTQA+ Youths

LGBTQA+ young people aged 16 to 21 years were invited to participate in individual, semistructured, in-depth interviews. Interview questions (Multimedia Appendix 1) were structured similarly to focus group items and aimed to explore 2 main domains: contemporary sources of stress experienced by LGBTQA+ young people and potential areas for making the OurFutures Mental Health program more affirming, inclusive, and supportive of LGBTQA+ young people. Young people were recruited through social media (Twitter; Twitter, Inc, subsequently rebranded as X and Facebook; Meta Platforms, Inc) and professional networks of youth and LGBTQA+ organizations. Interviews were conducted over Zoom or WhatsApp text messaging (participant's choice) and lasted for approximately 1 hour. These online channels were chosen as they offer LGBTQA+ young people increased flexibility, confidentiality, privacy, and anonymity to overcome key barriers to participation, including travel, cost, and parental support [51,52]. Interview participants were reimbursed with an Aus $20 (US $13.17) for their time. Interview facilitators had a script but had the flexibility to explore participant responses in depth and ask follow-up questions based on participant responses. Interviews were recorded and transcribed, and summative content analysis was conducted.

Stage 3: Clinical Psychologist Review of All Program Materials

From April to July 2023, a clinical psychologist provided an in-depth review of all program material to enhance readability (condensing text and simplifying language); improve utility (increasing use of role modeling techniques by characters) while preserving key CBT elements; and remove focus on overt symptoms and disorders, instead normalizing general stress and worry or feeling low; and differentiating between the universal experience of emotions and mental disorders, such as anxiety and depressive disorders [22]. The psychologist review also incorporated considerations of safety and privacy, suggestions for trauma-informed content, and reviewing trauma-informed refinements (refer to the Stage 4: Expert Team Consultation and Literature Review section).

Stage 4: Expert Team Consultation and Literature Review

From April 2022 to May 2023, a team of 12 research experts in adolescent mental health and a clinical psychologist engaged in fortnightly consultations on the intervention adaptation. Aligning with contemporary discussions regarding the future of universal, school-based mental health prevention programs, the team conscientiously discussed potential strategies to avoid potential iatrogenic harms associated with the program [21], including normalizing difficult emotions, discussing character examples rather than personal examples, and offering strategies for personal reflection and skills practice as optional and for discretionary individual use out of class. Discussions focused on the latest literature and findings from school-based universal mental health trials [19,23,37,40], as reviewed in the introduction of this study. These consultations drew on the latest evidence for trauma-informed prevention [53-55]. Specifically, these drew on 2 systematic reviews of the literature, which identified intervention targets to prevent psychopathology for young people exposed to trauma, as well as existing trauma-informed mental health prevention programs for young people aged 12 to 24 years [56,57].

Finally, consultations centered on restructuring the existing program and adapting it in line with the youth feedback described in stages 1 and 2.

Formative findings and insights from the aforementioned stages were collated and iteratively discussed among the research team. Adaptations were subsequently made to the OurFutures Mental Health intervention relating to the delivery of therapeutic content (classroom materials and take-home activities), storylines, and cartoons.

Results

Stage 1: Analysis of Evaluation Data From the Original Climate Schools Mental Health Program

Textbox 1 presents the identified areas for improvement arising from the formative evaluation and the corresponding intervention adaptation undertaken. Full results of the formative evaluation are presented in a separate publication [27]. Briefly, while most (453/759, 59.7%) students rated the OurFutures Mental Health program as good or very good, a considerable proportion of students did not perceive the original storylines to be relevant and were unsure whether they were likely to use skills and information from the program in their own lives (370/758, 48.8% and 290/757, 38.3%, respectively). Female participants were less likely to perceive the storyline as relevant compared with their male peers. Adjusting for participants' sex, participants with either probable anxiety disorder, probable depressive disorder, or elevated levels of emotional symptoms were significantly more likely to enjoy the project storylines compared with their peers without these 3 respective conditions [27].

Five broad themes emerged from participants' survey responses to open-ended questions regarding potential areas for improvement: (1) making content more realistic and relatable; (2) ensuring that the content is engaging and entertaining; (3) ensuring that the content covers wide aspects of mental ill-health, such as adversity, stigma, and diversity; 4) reducing the length of the program; and 5) ensuring that the materials are age appropriate.

Textbox 1. Areas for future improvement identified in previous program iteration.

Focus areas

- The stories seemed unrealistic or unrelatable, for example, having cognitive behavioral therapy skills delivered by 1 of the peer characters in the cartoon (Chloe, a student aged 14 years).
- The content was not engaging and entertaining.
- The program did not adequately cover the realities of living with mental ill-health, including adversity, stigma, and diversity.
- There was too much information, and the program was too lengthy.
- The content seemed to be aimed at younger audiences.

Stage 2.1: School-Based Focus Groups (General Population of Adolescents)

Three in-depth focus groups were conducted in 2 secondary schools in Australia, with youths aged 13 to 15 years (n=39). Predominant responses to the research questions eliciting the main causes of stress among Australian youths, ways of coping, and topics they believe should be covered in a mental health program are presented in Textbox 2 and Multimedia Appendix 1.

Some of the students' comments vividly described scenarios reflective of contemporary causes of stress and coping strategies. For example, 1 participant noted that "lash[ing] out... is a very common experience." Another focus group participant raised that "a lot of young people today report feeling rushed...." These discrete comments were addressed through specific changes and adaptations in the cartoon and learning materials. Other responses, which were more intangible and commentary in nature, were accordingly absorbed into the team's general outlook and approach to the intervention adaptation process. For example, when describing the therapeutic experience of successfully coping with a difficult time, 1 focus group participant described it as "...doing things so you can feel like out of your reality."

In addition to the common sources of stress mentioned above, focus group participants also identified discrete aspects of the OurFutures Mental Health cartoons and storylines that would benefit from improved relevance. These areas for improvement are listed below in Textbox 3.

Textbox 2. Focus group participants' common sources of distress, ways of coping, and topics they believe should be covered in a school-based mental health program.

Research questions and responses

- Concerns
  - Bullying
  - Gender and sexuality diversity
  - School work and pressures, for example, deadlines, time management, managing cocurricular activities, and relationships on top of school
  - Parent expectations
  - Sport (eg, how well you perform and relationships with members of the team)
  - Relationships, particularly peer relationships
- Ways of coping
  - Try not to think about it
  - Talking with friends
  - Seeking help from a professional (eg, psychologist)
  - Finding someone you can talk to who understands you
  - Telling someone (instead of being mean back, eg, bullying)
  - Being around supportive friends
  - Social media and games
  - "Breathing tricks to help"
  - Taking a broader perspective
  - Preparing the best you can
  - Avoiding distractions
  - Breaking things up with a run or seeing friends
  - Letting things go
  - Listening to each other
  - Asking for advice
- Topics and issues
  - Social media
  - How to be assertive
  - False information (eg, rumors), social media depictions, stereotypes, and stigma
  - How to seek help from an adult
  - Substance use, especially vapes
  - Diverse representations of gender and sexuality
  - Normalization of gender and sexuality diversity
  - Combating transphobia and racism
  - Trauma
  - Time management
  - Planning activities
  - Important role of friendships
  - Lack of support from friends
  - How to have and "manage" healthy relationships with friends
  - Mindset

Textbox 3. Focus group participants' suggestions for improvement.

Suggestions

- Remove curfew for characters as this is not realistic for young people, who are more likely to communicate with their parents via phone about where they are and what time they will be home.
- Need to increase engagement
- Trans and gay people in modules should "just be there" and not be different.
- Characters looked like Disney princesses. Clothes were "basic" and not realistic.
- Gender stereotypes of boys going to the beach and girls hanging out at home should be avoided.
- Inclusive, stigma-free language around mental health should be used.
- Animations appeared dated

Stage 2.2: Consultations With an LGBTQA+ YAC

Insights drawn from YAC meetings and accompanying field notes were distilled into key recommendations that were adopted by the researchers in their approach and activities to ensure that all program content and materials are affirming, inclusive, and supportive of LGBTQA+ young people and gender and sexuality diversity more broadly. These guiding principles and key recommendations are detailed in Textbox 4.

Textbox 4. Guiding principles and recommendations for making universal mental health prevention programs inclusive, supportive, and affirming of lesbian, gay, bisexual, transgender, nonbinary, queer, questioning, and otherwise gender and sexuality diverse (LGBTQA+) young people, as described by the LGBTQA+ youth advisory committee.

Guiding principles and recommendations

- LGBTQA+ young people experience life unrelated to their gender and sexuality.
  - Produce narratives that do not center LGBTQA+ young peoples' storylines around their gender and sexuality.
- Being inclusive of LGBTQA+ young people means letting LGBTQA+ young people "casually exist," that is, "inclusion through normalisation."
  - Normalize gender and sexuality diversity for an LGBTQA+ character by not making gender and sexuality a focal part of their personality.
- Avoid tokenistic stereotypes but portray genuine "touchstones" of trans and queer cultures.
  - Draw from real-life experiences to create authentic, relatable depictions of LGBTQA+ young people.
- Queer and transgender identities are diverse and intersectional.
  - Ensure representation of less represented LGBTQA+ young people, including trans and nonbinary people, as well as LGBTQA+ young people at different stages of their identity (eg, questioning).
- Queer and transgender identities cannot be seen by other people unless you choose to express and "show" it.
  - Ensure all storylines and characters reflect the complex nuance of gender and sexuality diversity rather than inauthentic, simplistic, or tokenistic expressions.

Stage 2.3: Interviews With LGBTQA+ Youths

Two LGBTQA+ youths, a gay transgender boy and a bisexual cis girl, consented to participate in interviews via WhatsApp text messaging and Zoom videoconferencing, respectively. Interviews highlighted how isolation is a common issue for LGBTQA+ young people. Moreover, both participants reflected on how their families and friends represented major support systems. For example, 1 participant noted:

> *I have my support systems for when I feel unsafe but I think the majority of the time there's only avoidance.*

Both participants noted that their sexuality and gender were not causes of distress but rather prejudice and discrimination from others due to their sexuality and gender caused distress. In addition, both participants noted that the current materials did not make any mention or representation of gender and sexuality diversity, with 1 participant suggesting that "...seeing other queer people comfortable and thriving is all a lot of kids need." Input from these interviews was combined with feedback from the YAC consultations (refer to the Stage 2.2: Consultations With an LGBTQA+ YAC section) to adapt the intervention accordingly.

Stage 3: Clinical Psychologist Review of All Program Materials

The review by a clinical psychologist was driven by key guiding principles and accompanying recommendations, as shown in Textbox 5.

Textbox 5. Guiding principles and recommendations following clinical psychologist review of the program materials.

Guiding principles and recommendations

- Difficult emotions are experienced by everyone and have a normal ebb and flow, just as pleasant emotions do. Emotions are informative.
    - Avoid pathologizing difficult emotions.
    - Acknowledge that while emotions can be unpleasant, they can also be informative.
    - Promote student understanding of emotions by encouraging them to think of other words to describe their emotions, for example, the color wheel.
    - Language such as “activities to combat depression” should be avoided. Provide coping strategies along with the knowledge that these are not intended to remove uncomfortable emotions but rather help tolerate when they are overwhelming.
- How we cope with our emotions and thoughts is important; this is the difference between low mood and depressive disorder and anxiety and anxiety disorder.
    - Educate students on the difference between the symptoms and a disorder. Reinforce that all students experience difficult emotions, but not all students experience depression or anxiety.
    - Provide strategies to promote healthy ways of coping when we inevitably experience periods of feeling anxious or down.
    - Include behavioral activation strategies to promote functioning when feeling low or anxious.
- Stressful life events have a strong impact on the symptoms of depression and anxiety.
    - Include psychoeducation, resources for teachers, and details of support services.
    - Reduce the focus on the individual and educate students on the social determinants of health and trauma. This will hopefully reduce shame, stigma, and self-stigma.
- Adolescent depression often includes dysregulated emotions, labile mood and can include suicidality and self-harm [58].
    - Provide guided examples to self-regulate in times of high emotions, such as breathing exercises, progressive muscle relaxation, and emotion surfing for all students and optional additional strategies, such as soothing activities and grounding techniques.
- There is a huge individual variability in strategies that young people find helpful for managing strong emotions [20,59,60]. Finding strategies that work for oneself enables empowerment and autonomy, which are key to adolescent development.
    - Make all skills practice apply to the cartoon characters, with any self-applied skills training to be optional only. Students do not have to discuss and practice their own experiences in class (also recommended from a trauma-informed perspective, see Stage 4: Expert Team Consultation and Systematic Reviews) but can learn the skills through peers in the cartoon characters and then can choose to use the strategies in their own time.
    - Rather than being prescriptive, phrasing refers to trying different strategies to see what helps them, and the characters use different types of strategies. This reinforces that not everything works for everyone and is hoped to reduce feelings of hopelessness if certain strategies do not help.
- Students have incredibly varied lived experiences, which influence their mental health in myriad ways.
    - Scenarios used in class activities apply to the cartoon characters only. Students only apply skills to their own personal scenarios in the privacy of their own homes. This is hoped to reduce the negative impact of social comparison, whereby students who experience elevated depressive symptoms may feel more isolated and concerned whether the other students in the classroom reflect on their own experience of never having experienced elevated symptomatology.
- Sources of support are crucial
    - Modeling characters seeking support
    - Ask students to write down the name of someone who they could talk to about a problem they are currently facing, or if they cannot think of anyone, a service from one of those provided to them in the program that they could call. Identifying the barriers to reaching out to this person to talk to them about the problem they are facing and some things they could do to overcome this barrier

Stage 4: Expert Team Consultation and Systematic Reviews

Program adaptation drew on the findings from 2 systematic reviews conducted from 2021 to 2023 and consultations among expert researchers and clinicians in the fields of childhood trauma and youth mental health. These systematic reviews identified intervention targets to prevent psychopathology for young people exposed to trauma, as well as existing trauma-informed mental health prevention programs for young people. Full details of these reviews are available elsewhere [56,57]. Guiding principles and recommendations derived from this literature and team consultations are presented in Textbox 6.

Textbox 6. Guiding principles and recommendations regarding embedding trauma-informed principles within the modified OurFutures Mental Health program generated from expert team consultation and systematic literature reviews.

Guiding principles and recommendations

- Trauma-informed practice recognizes the impact, signs, and symptoms of trauma; resists retraumatizing clients or students; and integrates understanding of trauma into practice and policies [61].
    - Traumatic events are commonly faced by young people and should be represented in program content. Psychoeducation around the impact of trauma on mental health and common signs and symptoms of trauma exposure should be included in accompanying student and teacher lesson summaries.
    - School practices and policies play an important role in avoiding retraumatizing youth affected by trauma. For example, disciplinary practices that provide support rather than exclusion (eg, suspension) reflect trauma-informed practice.
    - Provide information to teachers before program commencement via teacher summaries.
    - All skills practice in the classroom apply to the cartoon characters. Students do not discuss their personal experiences or practice skills for their own situations in class, where they may not feel safe (due to peers and teachers). Instead, skills are learned through the cartoon characters, and students can choose to access the optional, at-home activities to apply the skills to their own scenarios.
- Many young people exposed to traumatic events do not develop mental health problems. Trauma should not be considered deterministic of mental illness. The individual and social resources available to someone exposed to trauma can affect the development of mental ill-health.
    - Include information for teachers on the link between trauma and mental health and that it is not deterministic in the teacher summaries.
    - Provide psychoeducation material to students, illustrating the interconnected relationship between thoughts, feelings, and actions.
- Exposure to adversity can impact one’s ability to regulate their own emotions.
    - Empower students with skills of soothing, grounding techniques, imagery, and visualization techniques.
- There is a diverse range of exposures to adversity that impact young people differently.
    - Represent a range of adversities in the program content, for example, bullying, domestic violence, and gender-based and sexuality-based discrimination.
    - Similarly, represent a range of reactions, including feeling sad or down, anxious, and dysregulated.
- Safety is the first priority.
    - Consistently encourage young people to talk to a trusted adult when faced with traumatic or adverse experiences. List examples of trusted adults to whom they can reach out, for example, a school counselor, teacher, parent, or other relative. Provide information and contact details for third-party support services.
- The impacts of trauma can be long term, affecting attribution styles, emotions, and behaviors. There are high levels of shame and self-criticism in adolescents, especially for those exposed to adversity and discrimination.
    - Reflect on how experiences of past adversity can affect how we perceive ourselves, the world, and our relationships. Incorporate skills training and practice for students to identify thinking traps and challenge these with more helpful and realistic ways of thinking. Encourage self-compassion through student activities.

Adapted OurFutures Mental Health Module

In response to the youth perspectives and guiding principles described in Textbox 6, the following adaptations were made to the OurFutures Mental Health program. Storyline dialogue and lesson content were reduced in length (quantity and overall time taken to complete).

Storylines

To reflect best-practice principles of trauma-informed approaches to prevention (Textbox 6), the research team carefully expanded 2 characters’ storylines, including Will and Chloe, to reflect the backgrounds of domestic violence and bullying, respectively, in an authentic, trauma-informed manner. These 2 specific experiences reflect the most commonly experienced adverse events by young people in Australia [62,63] and are strongly associated with mental ill-health and substance use [53,64,65]. In addition to these major changes, several minor modifications were made to the program storylines:

- Elements of drama in the storyline (eg, friendship conflicts and suspenseful romance) were increased, and dialogue was significantly shortened to increase student engagement.
- Several key expansions were made to characters’ storylines to include more diverse life experiences. These include themes of bullying, domestic violence, household dysfunction, and identity exploration. More diverse representations of depression and anxiety, incorporated issues of stigma and discrimination, the role of friendships, and the physiological aspects of anxiety were included.
- School stress and time management were made central and peripheral themes in all main characters’ storylines.
- Scenes were revised and café and skate park (gender-neutral) settings were introduced. Transgender nonbinary queer character, Julia, was included in both.

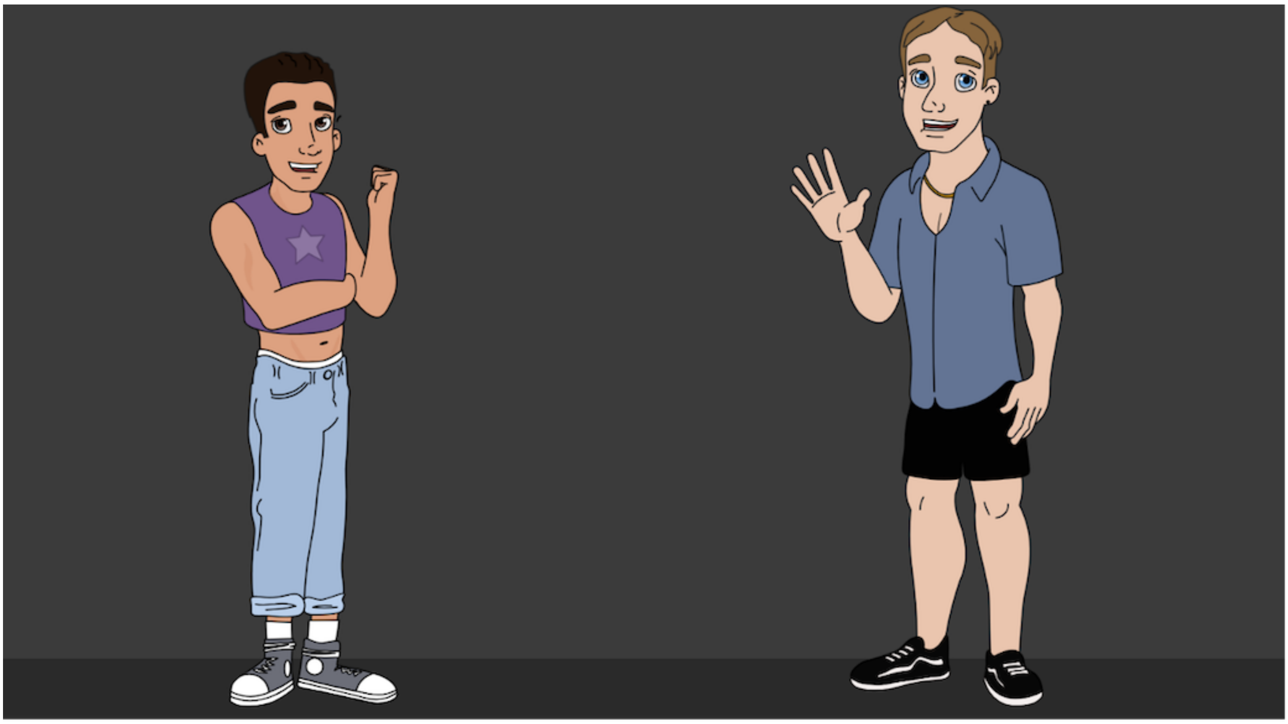
- Material was revised to remove curfews within characters' storylines.
- Two new narrators were introduced to add more layers to the main characters' respective storylines through focalizing narration from an outside character.
- Themes of peer relationships and intimate partner relationships were embedded and maintained throughout all character storylines.

Characters

Combining insights from interviews and consultation with LGBTQA+ youths, 3 new characters were created with the help of a professional graphic designer, reflecting a variety of genders, sexualities, and cultural backgrounds, whose mannerisms and clothes were inspired by contemporary media personalities. These new characters are displayed in Figures 1 and 2.

Figure 1. New character in the revised OurFutures Mental Health program: Julia.

Figure 2. New narrators in the revised OurFutures Mental Health program: Alex and Ryan (Alex presented in the left and Ryan in the right).



Julia is a transgender nonbinary queer person who is the love interest of Ella, a queer girl. Through normalizing Ella’s attraction to a transgender nonbinary queer person, these characters strive to normalize attraction, behavior, and feelings without self-doubt, self-stigma, and gatekeeping. Alex is a “femme slay queen of colour,” and Ryan is a “stereotypically hegemonically masculine-looking bro.” Together, this duo are the new story narrators who previously attended the same school as the other characters. This configuration was intentional to elevate voices within LGBTQA+ communities that have been historically underrepresented (eg, LGBTQA+ young people of color) to break down stigma and barriers to friendship and to demonstrate connection irrespective of gender and sexuality diversity. The appearances of these characters were inspired by popular television shows, including LGBTQA+ mainstays: the *Queer as Folk* reboot and *Heartbreak High*.

Feedback during stages 2.2 and 2.3 emphasized that LGBTQA+ young peoples’ stories in the past have largely revolved around surviving dysphoric adversity rather than celebrating the positive, euphoric, and mundane aspects of LGBTQA+ young peoples’ lives. Hence, Julia’s storyline does not feature any aspect of hardship in relation to their gender journey.

In addition to the 3 new characters, several minor modifications were made to the remaining cast of characters, as listed below:

- Revisions of characters maintained cultural diversity among the cast of characters.
- More realistic, discreet clothing options were sourced from popular influencers and television actors on social media.

Weekly, Manualized Program Content (Universal)

In response to feedback sourced from stages 1 to 4, the following adaptations were made to the content:

- We moved psychoeducation from being delivered by peers to being delivered by new older narrator characters. These narrators are alumni of the main storyline high school setting, retaining a youth voice and allowing peer-led SMS text messaging.
- We changed the character of Chloe to seem less regimented and formally trained in the way that she spoke about mental health and more of a compassionate peer who is a good listener. This ultimately allowed Chloe to more realistically represent a young person aged 14 years.
- By virtue of revising all dialogue and program content to be trauma-informed, all language used was sensitive to the impacts of adverse life experiences and how this might impact mental ill-health.

A comparison of the program content between the original and updated program is presented below in Table 1.

In the original OurFutures Mental Health, the teacher or school staff member responsible for program facilitation was provided with optional activities to administer to students after completing the cartoon component of each lesson. By contrast, the updated classroom activities contain skills practice and are, therefore, not described as optional but rather a key component of the intervention. Classroom activities are a mix of individual activity-style questions and class discussion and brainstorming activities facilitated by the teacher intended to reinforce the key concepts introduced in the cartoon storylines and provide an opportunity for skills practice using the cartoon characters’ scenarios. For each lesson, classroom activities are provided to teachers via the teacher portal of the website. These activities focus on applying the CBT strategies covered in that week’s lesson to the cartoon characters, allowing students to practice the skills learned while minimizing the potential for uncomfortable feelings that might arise when students discuss or reflect on their own personal examples in class. This adaptation reflects principles of trauma-aware schooling, which asserts that schools should promote a sense of safety among students [66]. In addition, this level of skills practice was expected to be sufficient for most children who do not experience elevated mental health symptoms, thus improving the relevancy of the program for these students.

Table 1. Comparison of weekly program content in original and updated versions of the OurFutures Mental Health program.

Lesson	Original content	Updated content
1	• Identify the signs and symptoms of anxiety and depression.	• Highlight the difference between symptoms of low mood or anxiety and depressive or anxiety disorders. Remove statistics on the prevalence of depressive and anxiety disorders to avoid students pathologizing normal experiences and to improve relatability. Encourage students to think of other words to describe low mood and anxiety to demonstrate these are common and normal emotions. • Introduce the CBT[a] model to understand how the characters' thoughts, feelings, and physical sensations affect their behaviors. Show how the characters' exposure to adversity (eg, bullying and domestic violence) affects their mental health. • Introducing pronouns and information about experiences of gender and sexuality diversity
2	• Identify unhelpful thoughts and practice skills to challenge these thoughts. • Explore more realistic and helpful ways of thinking.	• Identify negative thinking traps (eg, mind reading and catastrophizing) and learning strategies to challenge negative thoughts. Apply realistic thinking practice to Will's and Ella's scenarios, where Will's scenario incorporates examples of applying self-compassion in light of adverse situation happening in his home life.
3	• Identify behavioral strategies to improve mood and enhance mental health. Practice implementing these strategies through activity scheduling and stepladders.	• General updates but no substantive changes to content or activities
4	• Learn and practice skills for assertiveness. Practice skills for coping with intense emotions, for example, controlled breathing and emotion surfing.	• Reflect that our past or current experiences affect how we perceive others' communication and actions. For example, a previous experience of bullying can influence how we perceive others' actions in the present. • Assertiveness and other skills practice retained from original content
5	• Structured problem-solving and behavioral experiments: learn ways to tackle daunting scenarios by breaking them into smaller, more manageable components, such as managing several assessments alongside part-time employment.	• General updates but no substantive changes to content or activities
6	• Review and help-seeking: promotes the importance of seeking help and reminds students of the support available. Review of strategies to address feelings of anxiety and low mood.	• General updates but no substantive changes to content or activities

[a] CBT: cognitive behavioral therapy.

Optional at-Home Activities (Proportionate Universalism)

In the refined OurFutures Mental Health program, teachers are encouraged to additionally direct students to optional "at-home" activities that are available to download in the student portal of the website. In these activities, students are provided with psychoeducation focused on coping with adversity or traumatic events, seeking support, prioritizing safety, gender and sexuality diversity broadly, and support services specific to LGBTQA+ young people. These activities encouraged students to apply the strategies and coping skills learned in that week's lesson to themselves and their own scenarios. These included activities such as grounding exercises, soothing activities, imagery, and self-compassion. Teachers were informed that these activities were to be accessed by students outside of class time to ensure that this self-practice was voluntary and confidential. Specific content is presented in Textbox 7. These opt-in at-home activities were introduced to facilitate a restructuring of the program to provide low-intensity therapeutic content to *all* students, including students not exhibiting mental ill-health symptoms, while providing greater-intensity therapeutic content to students who might need it. Therefore, aligned with the concept of proportionate universalism, these optional activities facilitated an "opt-in" increased intervention dosage for students who perceived the need or wanted additional information and skills training while retaining a low-dose, universal mental health intervention for delivery within schools.

Textbox 7. Summary of optional, at-home activities available to students.

Summary

- Psychoeducation: apply the cognitive behavioral therapy model to self to identify the thoughts, feelings, and behaviors associated with recent feelings or low mood or anxiety and identify ways of coping with these. Identify which of these ways of coping were helpful or unhelpful. Provide psychoeducation about stressful life events, stigma and discrimination, and our environment on mental health. Identify sources of support for managing mental health and provide contact details for third-party support services.
- Cognitive strategies: apply realistic thinking and thinking traps to the student's own personal example.
- Behavioral strategies: complete behavioral strategies for oneself, for example, stepladder and activity scheduling.
- Assertiveness training: practice assertiveness in response to a situation the student is currently facing (or using an example from the past). Introduce and practice additional strategies (than those provided in the universal content) to cope with intense emotions, for example, grounding, soothing, imagery, and self-compassion. Encourage students to select and try some of these strategies and record which ones they found helpful.
- Problem-solving: apply structured problem-solving to a problem the student is currently facing (or one from the past). Encourage students to reflect on their progress or the success of their structured problem-solving attempt after they enact the solution they came up with and try a different strategy if needed.
- Review and sources of support: review the techniques and strategies learned throughout the program. Record sources of support available to the student and encourage them to identify barriers to reaching out to this person and ways to overcome barriers to reaching out.

Weekly Student and Teacher Lesson Summaries

Student and teacher lesson summaries were updated to include more guidance on trauma and gender and sexuality diversity, including the relationships between traumatic events and gender or sexuality stigma and discrimination on mental health; inclusive, trauma-informed language regarding gender and sexuality; and what schools and teachers can do to support the mental health of their students, particularly LGBTQA+ students and students exposed to adversity.

Quiz Questions to Reinforce Material

Multiple-choice quiz questions at the end of each module were also modified to reinforce key concepts regarding problem-solving skills, coping skills, and the interconnectedness of thoughts, behaviors, and emotions (eg, “True or false: Avoiding things you are anxious about can make anxiety worse in the long term.”). In addition, some items were included to promote principles of trauma-informed approaches, particularly related to recognizing the signs, symptoms, and impacts of exposure to adversity. Finally, quiz items were included that aimed to promote students' knowledge and acceptance of gender and sexuality diversity. The questions and answers specific to LGBTQA+ young people aimed to reinforce key skills of allyship, fostering acceptance, inclusion of LGBTQA+ young people, and affirming and validating LGBTQA+ young people. For example, 1 answer delivered by Josh is as follows:

> *Love is love! No matter if its cis people, hetero people, trans people, or queer people, relationships are the same for everyone.*

Discussion

Principal Findings

The updated OurFutures Mental Health program is a trauma-informed, LBGTQA+ affirmative program aligned with the concept of proportionate universalism. Program adaptations included (1) adding new characters and storylines to reflect gender and sexuality diversity and common adverse life events, youth perspectives, and expert advice; (2) updating teacher resources to include more guidance on trauma, guidance on LGBTQA+, and teaching social-emotional skills; and (3) restructuring the content in line with targeted universalism, by providing lower-intensity social-emotional skills and psychoeducation to all adolescents in the core modules or activities and additional content via voluntary, at-home activities (eg, LGBTQA+ and trauma resources and further skills for depression or anxiety). This universal, student-facing intervention will use proven strategies to enhance implementation and scalability in schools. This includes web-based delivery of the lesson content via a web portal, student and teacher summaries, and discussion guides (not requiring teacher training). The content of the program is also mapped to the Australian National Curriculum, allowing it to be embedded in teacher planning for mental health education.

The OurFutures Mental Health program adaptation responds to recent mixed findings of universal school-based mental health prevention programs, which include null, small beneficial, and small iatrogenic effects [19,20,23,37,42]. The reality of diverse school student populations presents a challenge for preventionists to ensure the relevance and utility of universal mental health prevention programs for all students. Our findings highlight that the heterogenous distributions of the severity of mental ill-health symptoms among young people are meaningful for how relevant and engaging universal mental health prevention programs are to end users [27]. This study highlights the importance of sourcing formative insights from a variety of stakeholders, especially young people themselves. Asking what works, for whom, and why it works is of crucial importance in determining the efficacy of prevention approaches [19,20].

The efficacy of the refined OurFutures Mental Health program is currently being tested through a cluster RCT with up to 1200 students in 12 schools across Australia [44]. We hypothesize that, compared with students in control schools, students in intervention schools will show improved mental health knowledge and reduced depressive and anxiety symptoms at 3 months after baseline. A planned subgroup analysis will also examine the program effects for those exhibiting elevated mental health symptoms at baseline, across the 3 main outcomes of knowledge, depression, and anxiety symptoms. Secondary outcomes to be measured include improvements in general well-being, help-seeking, and quality of life and reductions in psychological distress; functional impairment; social, emotional, and behavioral problems; and alcohol use. In conjunction with student-report indicators of mental health and well-being, the proposed trial will also administer brief evaluation surveys to students and teachers in intervention schools to assess their experiences (eg, perceived satisfaction, relevance, helpfulness of program materials, and potential areas for improvement) completing or delivering the OurFutures Mental Health program. Teachers in intervention schools will also complete weekly logbooks describing their implementation of the program and any associated barriers and facilitators. A formal process evaluation will analyze and summarize findings from both evaluation surveys and logbooks to identify areas for improved relevance and engagement in future program iterations, with particular attention to the acceptability and reception of intervention characteristics tailored to LGBTQA+ young people and young people exposed to adversity. These results will also be compared with process evaluation results related to the previous iteration of the program [27] to further identify strengths and weaknesses for future program design and adaptation.

The adaptation process described in this study is not without its limitations. First, focus groups with grade 8 students were conducted at 3 independent or private schools in Sydney, Australia, and only 2 LGBTQA+ young people agreed to participate in targeted interviews. While this overrepresentation of youth from independent schools, who are likely from higher socioeconomic backgrounds, and urban youth limits generalizability to diverse groups of youth, qualitative responses were detailed and aligned with evidence from national surveys on sources of concern among young Australians [67]. Similarly, the limited number of individual interviews with LGBTQA+ youth may not have captured the full diversity of experiences within this population. Future studies should aim to increase the sample size and diversity of students to allow for more generalizable findings. Second, there was a poor quality of audio recordings for certain focus groups, which, in turn, may have missed participant insights during transcription. Every effort was made to transcribe these focus groups accurately with careful double-checking of transcripts for quality assurance purposes. Ensuring high-quality recording equipment should be prioritized in future studies. Third, the original evaluation data sourced for stage 1 of the adaptation process are relatively dated (having been collected in 2015). The nonrepresentativeness of this cohort relative to more contemporary cohorts was mitigated by our sourcing of feedback from additional contemporary youth (stage 2). Finally, due to time and budgetary constraints, not all updates to cartoons could be executed.

Conclusions

To the best of our knowledge, our study is the first to represent a shift in thinking about the future of school-based, universal mental health prevention, adapting a universal mental health prevention program to be universally proportionate, thereby leveraging the strengths of both universal and targeted approaches. Specifically, our study thoroughly details the multistaged adaptation of a universal mental ill-health prevention program, OurFutures Mental Health, to be trauma-informed, LGBTQA+ affirmative, and relevant to contemporary youth, triangulating multiple sources of quantitative, qualitative, and evidence synthesis data. A school-based cluster RCT with grade 8 students in Australian secondary schools is currently underway to evaluate the effectiveness of the OurFutures Mental Health program for reducing depressive and anxiety symptoms and improving mental health knowledge. Our study proposes a novel solution to the global call to action issued to actors in the school-based mental health prevention space to decisively and innovatively respond and advance the current stalemate state of the literature to ultimately improve the mental health and well-being of young people in schools.

Acknowledgments

This research is funded by the Paul Ramsay Foundation and Movember Foundation. The funders had no input into any aspect of the study design; methodology, analysis, and interpretation; or the decision to submit results for publication.

The researchers would like to express their immense gratitude and appreciation for the many young Australians who generously shared their time, experiences, and perspectives during the course of this study. The authors especially extend their thanks to those young people who bravely shared their insights into how to make mental health prevention efforts more trauma-informed and lesbian, gay, bisexual, transgender, queer, asexual affirmative. Finally, the authors humbly acknowledge and thank all past academicians, clinicians, young people, collaborators, and professional staff involved in the design, implementation, and evaluation of the past lives of the OurFutures Mental Health program.

MT and NCN are 2 of the developers of the OurFutures programs (formerly Climate Schools) and members of the OurFutures Institute, a not-for-profit charity, to distribute the OurFutures programs and maximize social well-being.

Conflicts of Interest

MT and NCN are cofounders of the OurFutures Institute. There are no other conflicts of interest to declare.

Abstract

Background: Preventive interventions are needed to provide targeted health support to adolescents to improve health behaviors. Engaging adolescents in preventive interventions remains a challenge, highlighting the need for innovative recruitment strategies. Given adolescents' lives are intertwined with digital technologies, attention should be focused on these avenues for recruitment. The evolving nature of clinical trials, including the emergence of virtual clinical trials, requires new recruitment approaches, which must be evaluated.

Objective: This study aimed to examine the effectiveness and cost of various digital recruitment strategies for recruiting adolescents to a virtual clinical trial, evaluate the progression of participants from screening to enrollment, and explore factors associated with nonparticipation. This was conducted using data from the Health4Me Study, a preventive digital health intervention to improve physical activity and nutrition behaviors among adolescents aged 12 to 18 years.

Methods: Participants were recruited into the Health4Me Study via social media advertisements on various contemporary platforms, emails to schools, emails to contacts within known networks, and emails to relevant youth organizations. Data were collected from social media advertisements, screening, and recruitment logs. Data analysis included summary and descriptive statistics, as well as chi-square tests to explore factors associated with nonparticipation.

Results: From 2369 expressions of interest, 390 (16.4%) participants were enrolled. A total of 19 advertisements were placed on social media, and 385 promotional emails were sent to schools, contacts within known networks, and relevant youth organizations. Social media advertisements reached 408,077 unique accounts. Advertisements mostly reached those living in populous states in Australia (306,489/408,077, 75.11% of unique accounts) and those identifying as female (177,698/408,077, 43.55% of unique accounts). A total of 24.97% (101,907/408,077) of advertisements were delivered to accounts with uncategorized genders. The total cost per participant enrolled was Aus $3.89 (approximately US $2.58). Most participants (1980/2305, 85.90%) found out about this study through Instagram. Differences in screening characteristics between eligible participants who did and did not enroll were found to be statistically significant for gender (*P*=.02), with fewer males and more individuals reporting their gender as "other" enrolling than expected by chance alone. The recruitment method also differed (*P*<.001), with fewer participants enrolling through Instagram and more enrolling through other methods (eg, known networks or word of mouth) than expected by chance alone.

Conclusions: This study found that virtual clinical trial recruitment was found to be low-cost, with the potential to increase trial participation. Social media was the most effective recruitment method, reaching all states and territories, including hard-to-reach populations. Future action is needed to explore recruitment methods that are more effective for males and to build trust among adolescents regarding clinical trial recruitment via social media.

KEYWORDS

adolescents; clinical trial; recruitment; digital health; prevention; adolescent health; health behavior change; health promotion; social media

Introduction

Adolescence is regarded as the second window of opportunity—a critical period to intervene and provide targeted support to improve health outcomes that have a profound impact on health and well-being throughout the life course [1]. Failure to invest in primary prevention among today's adolescents will increase the burden of chronic diseases and the existing sizable total health expenditure of Aus $24 billion (approximately US $15.9 billion) on potentially avoidable risk factors [2]. It is important that high-quality public health interventions that focus on primary prevention of chronic diseases are tested with adolescents through clinical trials. However, challenges exist with engaging adolescents in preventive interventions, including their health system disengagement making them hard to access for delivering such interventions [3], a prevention lens not being appealing to adolescents [4], and their evolving need for autonomy in providing informed consent [5]. Innovative methods to engage adolescents within preventive interventions are needed that can overcome identified barriers.

Adolescents' lives are increasingly intertwined with digital technologies such as mobile phones and the internet [6]. With that comes the opportunity to harness developments in digital technologies for innovative preventive interventions [7]. The use of digital methods for recruitment to clinical trials is increasing in popularity and they are particularly beneficial for recruitment to online clinical trials. Previous research has focused on comparing social media or other digital strategies to traditional in-person recruitment [8-13], and the use of digital tools for recruitment and retention of clinical trial participants [14,15]. While research shows that digital recruitment strategies are effective compared to traditional in-person recruitment, limited research is available to understand the efficiency of digital recruitment strategies alone and their impact on clinical trial participants and investigators (eg, helping investigators identify eligible trial participants) [14]. A previous review identified that Facebook (Meta) is effective for recruiting adolescent participants [16], and a cross-sectional study revealed that the use of Instagram (Instagram from Meta) and Snapchat (Snap Inc) may also be useful and cost-effective to recruit young people to surveys [17], but limited evidence is available for the use of these contemporary platforms for adolescent recruitment to clinical trials. As more social media platforms become available and others diminish in popularity, it is crucial that research is undertaken to understand their effectiveness for recruiting adolescents to research.

Additional complexities occur when there are no physical recruitment sites, otherwise known as remote [18], decentralized [19], or virtual [20] clinical trials, from hereon in called virtual clinical trials. Virtual clinical trials can leverage digital technologies for participant recruitment and retention, enabling online consent for participants, on-time data collection, and delivery of the intervention that is convenient for participants, as they do not have to travel to a physical site [21]. Virtual clinical trials among adolescent participants have the potential to overcome some of the previously identified barriers, including reaching those who are disengaged with the health system and reaching adolescents directly [22,23], allowing them autonomy in making decisions about their health [24], including providing informed consent (depending on ethics approvals). However, there is limited research to understand digital recruitment strategies for clinical trials among adolescents. Furthermore, it is also important to understand factors that may cause eligible participants not to engage in digital preventive interventions. Reporting will enable future research to tailor recruitment toward the most effective digital strategies and address factors that cause disengagement. Therefore, this study aimed (1) to examine the effectiveness and cost of various digital recruitment strategies for recruiting adolescents to a virtual clinical trial, (2) to evaluate the progression of participants from screening to enrollment, and (3) explore factors associated with nonparticipation.

Methods

Study Design

The Health4Me study was used as the context for this research. The full protocol is published elsewhere [25]. In brief, the Health4Me Study is a virtual clinical trial, based in Australia, of a community-based, 6-month text message intervention. The intervention aims to improve physical activity and nutrition behaviors among adolescents aged 12 to 18 years.

Ethical Considerations

Primary ethics approval was received from the University of Sydney Human Research Ethics Committee (2022/402), and the trial is registered at the Australia New Zealand Clinical Trials Registry (ANZCTR; ACTRN12622000949785; date registered: July 5, 2022).

Participants and Eligibility Criteria

Participants were eligible to take part in the Health4Me Study if they were (1) aged 12 to 18 years, (2) owned a mobile phone capable of sending and receiving text messages, (3) had an

Australian mobile phone number, (4) had sufficient English proficiency to read text messages pitched at a 7th grade reading level, and (5) provided electronic consent (or from their parents or guardians if they were aged <14 years). Participants were excluded from this study if they (1) had a diagnosis of type 1 or type 2 diabetes mellitus, (2) had a previous or current diagnosis of an eating disorder or were at high risk for an eating disorder as assessed in screening, (3) weighed <25th centile for their age, (4) had recent rapid weight loss, (5) had a medical condition that would preclude providing informed consent or ability to comply with this study's protocol, (6) were enrolled in an alternative randomized lifestyle management program, (7) were pregnant or planning to become pregnant during the 6-month intervention, and (8) were unable to read English at a 7th grade reading level. The eligibility criteria for the Health4Me Study have been published elsewhere [25].

Given the Health4Me Study was conducted virtually, several steps were embedded to ensure participants could safely enroll into this study. To complete screening procedures, the research team partnered with the InsideOut Institute for Eating Disorders, a team of researchers and clinician experts in eating disorders based at the University of Sydney. Potential participants first expressed interest to take part in this study by filling out the Expression of Interest (EOI) form on REDCap (Research Electronic Data Capture; Vanderbilt University), which included contact details and screening against the eligibility criteria, as well as screening for eating disorder risk using two validated questionnaires—InsideOut Institute Screener (IOI-S) and Eating Disorder Examination Questionnaire (EDE-Q) [26,27]. Study specific cut points were set for the IOI-S (≥16) and EDE-Q (>3 and any of behavioral questions 15 - 18 endorsed ≥1). Potential participants first completed the IOI-S, if they scored below the cut point and met all inclusion criteria, they were sent the e-consent form. However, if participants scored above the cut point on the IOI-S, they were directed to complete an EDE-Q. If potential participants scored under the cut point on the EDE-Q, they were deemed eligible and sent the e-consent form. If a potential participant was detected to be above the cut point on the EDE-Q, they were referred to the InsideOut Institute for Eating Disorders for an assessment to determine suitability to participate by eating disorder expert clinicians (clinical psychologist or registered clinical psychology students with expertise in eating disorders) via phone call. If they received clearance from the eating disorder expert clinicians, they were sent the e-consent form and deemed eligible to enroll in this study. If they did not receive clearance, they were sent an email with various resources for eating disorder support. If a potential participant did not meet other inclusion criteria, they were sent an email explaining why they were ineligible. All participants provided informed e-consent (and from their parents or guardians if they were aged <14 years) before baseline measures were collected [25]. Participants were randomized once all baseline measures were complete.

Recruitment

The protocol was to enroll 390 participants—195 per arm—based on detecting a mean difference in moderate to vigorous physical activity minutes per day of 14.8 (control: 42.55 and intervention: 57.36) with an SD of 21.45 for control and 37.79 for intervention or a 13.37% difference in the proportion of appropriate vegetable consumption (control: 4.85% and intervention: 18.22%) with 90% power and accounting for 30% dropout. The Bonferroni adjusted significance level of 0.025 was used to account for two primary outcomes. The participant information statement detailed that participants would receive an Aus $30 (approximately US $19.90) gift voucher at the completion of all baseline assessments as a reimbursement for their time. A recent review has suggested that financial incentives can be provided to children appropriately, and few studies suggest incentives are inherently harmful [28]. Recruitment methods are detailed below.

Recruitment Methods

Overview

Recruitment ran from February 2023 to February 2024 using a range of methods including social media advertising on Facebook, Instagram, TikTok, and Twitter/X, emails to schools, emails to contacts within known networks, and emails to relevant youth organizations. A dedicated study website was also created to establish legitimacy.

Social Media Advertisements

Initially, study-dedicated Facebook and Instagram pages were established with this study's logo, study contact information and detailed the purpose of this study. Posts were made on Instagram to establish this study as an authentic and active social media account. All content and this study logo were co-designed with adolescents [29]. All advertisements were created using ethics approved text and images on Meta Ads Manager, which simultaneously promoted advertisements on Facebook and Instagram or on TikTok for Business, which promoted advertisements on TikTok. Due to restrictions in advertising to people aged younger than 18 years [30], all advertisements were targeted only for people aged 13 to 18 years in Australia. Examples of the social media advertisements (images and text) are available in Multimedia Appendix 1. Advertisements on Meta were run for a maximum of 2 weeks, with a maximum budget of Aus $20 (approximately US $13.30) per day. The single advertisement on TikTok was run for 4 days, with a lifetime budget of Aus $50 (approximately US $33.20). A single post was made on Twitter/X by a member of the research team. All advertisements linked directly to this study EOI form, hosted on REDCap.

Emails

Emails were sent to schools, known networks and contacts of the research team and, relevant youth organizations, for example, headspace. Emails contained a link to this study's website and this study's REDCap page.

Study Website

Previous formative work by the research team revealed that adolescents desire online health information that is credible and reliable [31]. A study website was created to establish this study as legitimate and to build trust among adolescents. This study's website contained this study's logo, study contact information, detailed the purpose of this study, how to become involved (including a direct link to this study's REDCap page), photographs and names of the key researchers and names of the wider research team. Potential participants could also access the full participant information sheet through this study's website.

Data Sources

Social Media Advertisements

Data were available and collected from Meta Ads Manager. For each advertisement, data were collected on the number of days the advertisement ran, advertisement strategy used, reach, impressions, link clicks, cost per result, and total amount spent (Aus $). Deidentified advertisement audience demographic data included location, age, and gender. User's location was based on their state or territory (New South Wales [NSW], Victoria, South Australia, Queensland, Western Australia, Northern Territory, Tasmania, and Australian Capital Territory). Age and gender data were based on what social media users disclose on their user profiles and were summarized according to Meta Ads Manager categories (age: 13 - 17 or 18 - 24 years; gender: male, female, or uncategorized). Data were available and collected from TikTok for Business. For each advertisement, data were collected on the number of days the advertisement ran, reach, impressions, link clicks, cost per result, and total amount spent (Aus $). Post analytics were available and collected from Twitter/X. For the single post, data were collected on likes, reposts, impressions, and link clicks.

Recruitment Log

A log was kept of all dates on which emails were sent to schools, known networks and contacts, and youth organizations. Data were also collected on the number of people who visited this study's REDCap page each day to express interest and the number of enrollments. Detailed notes were kept on the log by the research team.

Screening Logs

A detailed log was kept of all participant inquiries. The secure online REDCap [32] database collected data, including age (12-14 years or 15-18 years), gender (male, female, other, or prefer not to say), high school attendance (yes or no), height and weight (for BMI calculations, categorized as underweight, healthy weight, above a healthy weight, or well above a healthy weight) [33,34], and recruitment method. The responses for recruitment method included (1) Facebook, (2) Instagram, (3) Twitter/X, (4) TikTok, (5) other social media platform, (6) headspace, (7) general practitioner or doctor, and (8) other. The screening log also contained details on eligibility and reasons for exclusion. A further screening log was also collected from the InsideOut Institute for Eating Disorders, which kept a detailed log of potential participants requiring screening for eating disorder risk. The secure online REDCap database allowed both the psychologists and research team to make comments. Potential participants were contacted a maximum of two times by the eating disorder expert clinicians. If contact was not established after two attempts, they were marked as ineligible and sent resources via email.

Data Analysis

Summary statistics regarding social media data are presented. Total costs (Aus $) are reported for social media advertisements, with the average cost calculated per participant eligible and per participant enrolled. Descriptive statistics for continuous measures, including counts and percentages for recruitment method, were used to summarize the breakdown of potential participants who inquired and participants screened by the InsideOut Institute for Eating Disorders.

To explore factors associated with nonparticipation, differences in screening characteristics between eligible participants who did and did not enroll in this study were compared using chi-square tests. The significance level was set at 5%. Characteristics included age, gender, BMI, high school attendance, and recruitment method. Adjusted standardized residuals (ASRs) were used to measure the strength of the difference between observed and expected values. Data were analyzed using IBM SPSS (version 29.0; IBM Corp).

Results

Effectiveness and Cost of Recruitment Strategies

A total of 2369 entries were made to the EOI form. Of those, 2305 respondents completed the question asking how they heard about this study. Most (1980/2305, 85.90%) found out about this study through Instagram, followed by other (182/2305, 7.9%) and then Facebook (112/2305, 4.9%). The full sample size of 390 adolescents was reached in 12 months.

For the Health4Me Study, there were 17 advertisements run on Meta Ads Manager over 12 months. The length at which the advertisements were running for ranged from 2 - 18 days, with advertisements running for a total of 146 days. Overall, advertisements reached a total of 408,077 unique Meta accounts and were viewed >2.3 million times. A cost-per-link-click strategy was employed in 16/17 advertisements, and one employed a cost-per-post-engagement strategy. Across 17 advertisements, 7211 link clicks were made. Advertisements mostly reached people in NSW, Victoria, and Queensland, accounting for 75.11% (306,489/408,077) of the audience. With regard to age, 96.89% (395,403/408,077) of the advertisement audience was 13 - 17 years old. For gender, advertisements mostly reached females (43.55%, 177,698/408,077); however, a quarter (24.97%, 101,907/408,077) of the advertisements were delivered to accounts with uncategorized genders. One advertisement was run through TikTok for Business, which ran for 4 days, reached 8386 unique accounts, and was viewed 14,832 times, with 144 link clicks made. No further data were available. One advertisement was placed on Twitter/X, which was viewed a total of 1041 times and reposted 11 times, with 15 link clicks made.

The overall cost of social media advertisements run through Meta was Aus $1478.63 (approximately US $965.69). Cost-per-link-click ranged from Aus $0.03 to Aus $0.87 (approximately US $0.02 to US $0.54). The overall cost of the advertisement through TikTok was Aus $39.97 (approximately US $26.10), with cost-per-link-click at Aus $0.28 (approximately US $0.18). In total, Aus $1518.60

(approximately US $991.80) was spent on social media advertisements. Cost per eligible participant was Aus $1.64 (approximately US $1.09), and cost per participant enrolled was Aus $3.89 (approximately US $2.58). A full breakdown of all social media data is available in Tables 1 and 2.

Emails requesting inclusion in school communications to students were sent to 367 high schools across NSW. One school announced this study at their school assembly. One email was sent to our mailing list of young people who have expressed interest in future research. Emails were sent to 17 other known networks, contacts, and youth organizations. Of those, the research team was made aware that one shared in their general practitioner newsletter, and one shared within their local health district. All sharing through schools, known networks, contacts, and youth organizations was at no cost to the research team.

Table . Breakdown of Meta advertisements reach by state or territory, age, and gender.

	Reach, n (%)
State or territory	
New South Wales	123,543 (30.27)
Victoria	95,954 (23.51)

[a] Post engagement: strategy aims to encourage users to like, share, comment on, or save the advertisement. Link clicks: strategy aims to encourage users to click on the advertisement URL link.

[b] Number of times the advertisement is delivered to a unique account.

[c] Number of times the advertisement is delivered in total (including being delivered multiple times to one account).

[d] The conversion rate over the time of the study was approximately Aus $1=US $0.65.

[e] Number of times the advertisement URL link was clicked.

[f] N/A: not applicable.

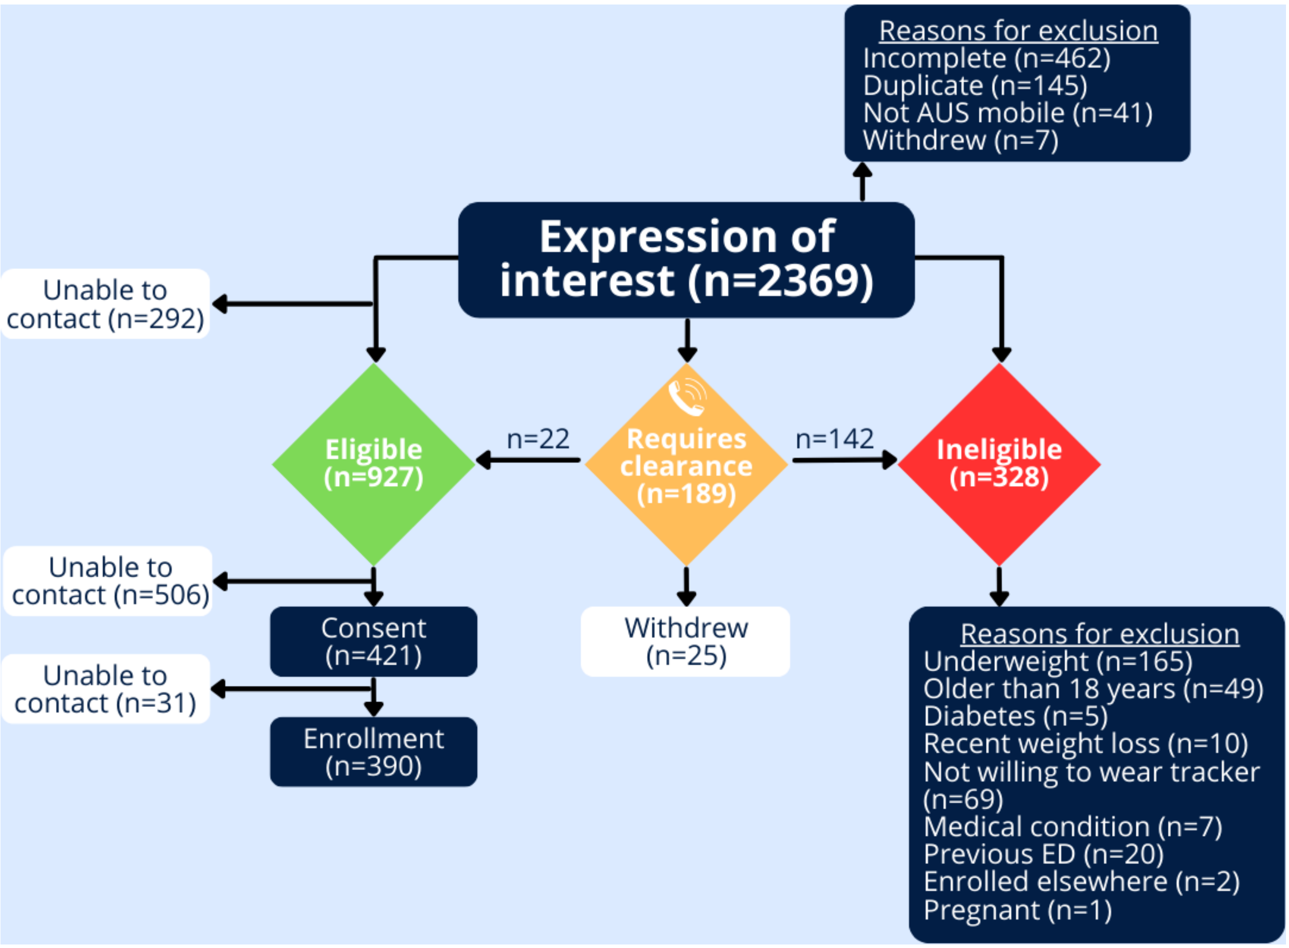
Progression of Participants From Screening to Enrollment

Figure 1 shows the progression of participants and dropout points from screening to enrollment. Of the 2369 entries on the EOI form, 655 were immediately excluded. Of the excluded entries, 41 did not have an Australian mobile number. These 41 entries were among the first 100 EOIs and were believed to be bots. After adding a reCAPTCHA to the REDCap screening survey, no further suspicious entries were received. Of the remaining, 462 entries were incomplete, 145 were duplicate entries, and 32 withdrew their EOI postscreening. In addition, 328 entries were ineligible, as they did not meet the inclusion criteria, with reasons for exclusion shown in Figure 1.

A total of 481 potential participants scored above the cut point on the IOI-S. A total of 292 participants were unable to be contacted to complete the EDE-Q (per protocol for further screening for eating disorder risk). A further 189 potential participants were referred to the InsideOut Institute for assessment from eating disorder expert clinicians. Of those, 104 were unable to be contacted by the eating disorder expert clinicians (and were therefore marked as ineligible), 38 were ineligible postcall as they were assessed as high risk. A further 25 potential participants withdrew at this step, and 22 potential participants were assessed as eligible by the psychologist and sent the e-consent form.

A total of 927 potential participants were eligible and sent the e-consent form. Of those, 506 were unable to be contacted and the e-consent form was never signed. The e-consent form was signed by 421 participants, and they were sent the baseline surveys, but 31 participants did not commence answering baseline questions, giving 390/2369 (16.4%) as participants enrolled in this study.

Figure 1. Progression of participants from screening to enrollment. AUS: Australian; ED: eating disorder.



Factors Associated With Nonparticipation

During screening, 537 potential participants were identified as eligible but did not proceed to enrollment, and 390 participants enrolled in the Health4Me Study. Chi-square tests indicated that there were statistically significant differences in screening characteristics between eligible participants who did and did not enroll in this study for gender and recruitment method. Gender differences were significant (χ^2_{3927}=9.8, *P*=.02); ASRs indicated fewer males and more individuals reporting "other" enrolled than expected by chance alone. Additionally, the recruitment method was significant (χ^2_{3925}=17.39, *P*<.001), ASRs indicated fewer participants enrolled through Instagram and more enrolled through other methods (eg, known networks or word of mouth) than expected by chance alone. No differences were observed for other screening characteristics. A full breakdown of screening characteristics between those who were eligible and did or did not enroll is available in Table 3.

Table . Comparison of screening characteristics between those who were eligible who did and did not enroll in the Health4Me Study.

	Total eligible and not enrolled (n=537)	Total enrolled (n=390)	Chi-square (*df*)	*P* value
Age (years)			3.8 (1927)	.05
12 - 14	80	41		
15 - 18	457	349		
Gender			9.8 (3927)	.02[a]
Male	166	92		
Female	347	274		
Other	11	17		
Prefer not to say	13	7		
BMI [b]			2.1 (3878)	.55
Underweight	21	16		
Healthy weight	410	279		
Above a healthy weight	60	51		
Well above a healthy weight	21	20		
Attending high school			0.5 (1927)	.82
Yes	464	339		
No	73	51		
Recruitment strategy [c]			17.3 (3925)	<.001[a]
Facebook	18	22		
Instagram	470	301		
Other social media platform[d]	4	5		
Other[e]	44	61		

[a] Statistically significant.

[b] Due to being asked gender during screening and not sex assigned at birth, we are unable to accurately calculate BMI for those who listed their gender as "other" or "prefer not to say."

[c] One record missing from each for recruitment strategy. Total eligible and not enrolled (n=536), and total enrolled (n=389).

[d] Due to small numbers, categories of Twitter/X, TikTok, and other social media platform were combined.

[e] Due to small numbers, categories of headspace, general practitioner or doctor, and other were combined.

Discussion

Principal Results

The Health4Me Study aimed at improving physical activity and nutrition behaviors among those aged 12 to 18 years. A total of 2369 EOIs were received, and 390/2369 (16.4%) participants were recruited in less than 12 months. Social media was the main source of recruitment. The research team did try to engage with schools, known networks, and relevant youth organizations via emails with limited success. Social media advertisements through Meta were effective, reaching 408,077 unique accounts across all states and territories in Australia. Overall, social media advertisements were low cost (Aus $3.89 per participant enrolled [approximately US $2.58]). From screening to enrollment, there were multiple points of dropout. Of the EOIs from potential participants who were eligible (927/2369, 39.1%), statistically significant differences were observed for those who did and did not enroll in terms of gender and recruitment method. Fewer males and more individuals reporting their gender as "other" enrolled than expected by chance alone. In addition, fewer individuals enrolled through Instagram and more enrolled through other methods (eg, known networks or word of mouth) than expected by chance alone.

Comparison With Prior Work

Virtual clinical trials have the potential to address challenges in traditional site-based recruitment and be cost-effective [20]. Yet, prevention programs among adolescents are known to have the lowest recruitment rates [35], and stakeholders have identified that a prevention lens may not be engaging for adolescents [4]. In the Health4Me Study, a digital preventive intervention, digital recruitment strategies that were employed were effective, recruiting 390 adolescents in less than 12 months. The Health4Me Study was guided by factors associated with successful recruitment from a previous virtual clinical trial [36], including (1) national recruitment, (2) self-referrals, (3) unmet need for trial intervention, (4) patient and public involvement, (5) regular monitoring and communication, and (6) reimbursement and early exclusion. In the Health4Me Study, a national sample was recruited and participants self-referred into this study. In addition, there are limited prevention programs currently available for adolescents [37], and the intervention and all advertising materials were co-designed with adolescents [29]. A small day-to-day research team was employed who communicated regularly through detailed screening and recruitment logs, and participants were reimbursed through online gift vouchers after completing all study activities at baseline and 6-month follow-up.

The costs reported in this study for social media advertising are lower per enrolled participant than what has previously been reported in reviews (approximately US $3-US $628) [9,38], however these studies mostly report on Facebook and compare social media to traditional in-person recruitment. Limited research is available reporting virtual clinical trial recruitment costs to recruit adolescents. A virtual clinical trial, which aimed to prevent and reduce cyberbullying among adolescents that used Instagram for study recruitment, found a higher consent rate than the Health4Me Study (24.4% vs 16.4%) yet had much higher social media advertisement costs (approximately US $19 versus approximately US $2.59 per enrolled participant) [39]. It is essential for future virtual clinical trials to report costs associated with recruitment to understand their cost-effectiveness for enrolling participants from the target population.

Virtual clinical trials allow remote access to research, potentially enhancing the diversity of participants, and recruiting from hard-to-reach populations [20]. In the Health4Me Study, it was observed that more individuals reporting their gender as "other" enrolled than expected by chance alone. This "other" category captures any gender other than male or female (eg, nonbinary or transgender). In another virtual clinical trial targeting cyberbullying found that nearly half of the participants recruited via Instagram identified as lesbian, gay, or bisexual [39]. It was also observed that less eligible males enrolled in the Health4Me Study than expected by chance alone. When looking at the social media advertisements, they reached less males overall. Evidence from large datasets demonstrates that females spend more time overall and more time per day on social media [40,41]. Additionally, another virtual clinical trial among an older population found that males were underrepresented [42]. Future efforts should be directed to identifying effective methods to recruit males to virtual clinical trials.

Another factor considered to attract hard-to-reach participants online is that those interested can self-refer into this study. A previous study, which aimed to assess effectiveness of online behavioral therapy for tics among young people, found that the majority of participants self-referred from online [36], enabling those who were not under the care of mental health clinicians to be included. The Health4Me Study is unique in that participants who are aged 15 years and older can consent themselves into this study, without the need for parent or guardian consent. This was approved by the ethics committee, with support from our youth advisory group as the Health4Me Study is a low-risk, preventive health intervention. This capacity to self-refer gives adolescents some autonomy around their health, especially given that preventive care is seldom given within primary care to this age group [43].

Within this study, less eligible adolescents enrolled through Instagram than were expected by chance alone, and more enrolled through other methods (eg, known networks or word of mouth) than what was expected by chance alone. Hypothesized reasons for this are around trust in health information that adolescents view online, adolescents being discouraged from sharing personal information online, and having poor knowledge and attitudes on clinical trials [44]. Previous reviews show that adolescents often distrust health information found online yet continue to engage with this information [45]. In terms of health information on social media, friends and networks are particularly important for gaining adolescents trust in this space [46]. Future studies planning to recruit adolescents through social media could explore the use of peer referral or endorsement from youth advisors or reputable organizations (eg, study sponsor) to gain an increased level of trust. In addition, adolescents are acutely aware of how their personal data are being used, and building trust and authenticity among this population is vital [31]. Partnerships with known youth health organizations and endorsement of the clinical trial through their own social media accounts may be useful to increase trust among adolescents.

Within the Health4Me Study, there were multiple points of dropout from screening to enrollment. The largest point of dropout was those who were eligible and sent the consent form but never responded. For all eligible participants, the research team sent the consent form twice via email, however after no response they were marked "unable to contact." Though emails are a highly acceptable form of communication among adolescents [47], future efforts should be directed to streamlining processes of screening and consent for scalability of future trials. Previous studies have aimed to do this using mobile apps, for example, ResearchKit (Apple Inc) [48], which is an open-source software framework designed to streamline the process of screening and consenting participants into research studies. Evidence of success is available for research studies among adults [49,50], yet no outcomes are currently available among adolescents [51]. Other strategies for enhancing communication with adolescents could also be explored in the future (with appropriate ethical approval), such as text messaging and direct messaging on social media platforms.

The second highest rate of dropout among participants was those who required further screening for a potential eating disorder. Out of 2369 potential participants, 292 (12.3%) did not complete an EDE-Q and were therefore excluded, and 189 (8.0%) required clearance through a phone call with this study's psychologist. When compared to the prevalence of eating disorders overall among Australian adolescents, this rate is lower than what has previously been reported (point prevalence of 22.2%) [52]. Thus, screening for eating disorders was not identified as a barrier to enrollment, rather an important safety precaution for potential identification of disordered eating among this population in a preventive intervention.

Limitations

Limitations in this study exist. First, this study is not representative of all adolescents due to inclusion criteria, which remove some groups. However, as this is a prevention intervention, the inclusion criteria aim to represent a large percentage of the adolescent population within Australia. Second, there are restrictions on advertising to adolescents via social media and changes are constantly occurring in this space. Though the inclusion criteria for age in this study was those aged 12 to 18 years, social media advertisements are unable to be targeted to adolescents aged younger than 13 years, as you can only establish a social media account if you are over 13 years. Advertisements were developed for distribution on Snapchat; however, advertising of clinical trials is not allowed on its platform. Therefore, recruitment of adolescents via social media is also a limitation to reaching adolescents aged <13 years. Third, adolescents report that they find recruitment via social media to be feasible and acceptable for recruitment and retention [53,54]. However, this was not assessed within this study as follow-ups are ongoing. Adolescent perceptions for using social media for recruitment will be assessed in the process evaluation for the Health4Me Study, by assessing retention rates and analyzing focus group data. The findings of this study require validation with studies among other adolescent populations and other types of interventions.

Conclusions

Within the Health4Me Study, it was observed that recruitment was most effective via social media, and this was low cost per participant enrolled. Throughout the screening to enrollment process, there were multiple points of dropout, and future efforts should be directed toward streamlining screening and enrollment processes for scalability of future trials. In addition, our results highlight the importance of building trust among clinical trials and health information generally among adolescents on social media for future success in recruiting adolescents via this digital strategy.

Acknowledgments

The team would like to acknowledge Jessie Zhou who assisted with participant screening and recruitment for the Health4Me Study. We would also like to acknowledge Dr Karen Spielman and Dr Kyra Sim from the Health4Me Steering Committee, and Teisha Schrimer from the Mid North Coast Local Health District, who were helpful in promoting this study among their known networks. We would also like to acknowledge Judith Fethney from the Susan Wakil School of Nursing and Midwifery for statistical support. The Health4Me Team is comprised of the following authors: Katharine Steinbeck, PhD—Specialty of Child and Adolescent Health, Westmead Clinical School, Faculty of Medicine and Health, The University of Sydney, Westmead, NSW, Australia; Gemma Figtree, PhD—Sydney Clinical School (Northern), Faculty of Medicine and Health, The University of Sydney, Sydney, NSW, Australia; Robyn Gallagher, PhD—Susan Wakil School of Nursing and Midwifery, Faculty of Medicine and Health, The University of Sydney, Sydney, NSW, Australia; Melissa Kang, PhD—General Practice Clinical School, Sydney Medical School, Faculty of Medicine and Health, The University of Sydney, Sydney, NSW, Australia; Karice Hyun, PhD—School of Health Sciences, Faculty of Medicine and Health, The University of Sydney, Sydney, NSW, Australia; Karen Spielman, MBBS (Hons)—InsideOut Institute, Faculty of Medicine and Health, University of Sydney, Sydney, NSW, Australia; Kyra A Sim, PhD—Metabolism & Obesity Service, Sydney Local Health District, Sydney, NSW, Australia; Tim Usherwood, MD—General Practice Clinical School, Sydney Medical School, Faculty of Medicine and Health, The University of Sydney, Sydney, NSW, Australia; Charlotte Hepse, MBBS (Hons)—The University of Notre Dame Australia, Sydney, NSW, Australia; Liliana Laranjo, PhD—Westmead Applied Research Centre, Faculty of Medicine and Health, The University of Sydney, Westmead, NSW, Australia; John Skinner, PhD—Djurali Centre for Aboriginal and Torres Strait Islander Health Research, Heart Research Institute, Sydney, NSW, Australia; Danielle Castles—Nepean Blue Mountains Local Health District, Penrith, NSW, Australia; Katrina E Champion, PhD—The Matilda Centre for Research in Mental Health and Substance Use, The University of Sydney, Sydney, NSW, Australia; Lauren A Gardner, PhD—The Matilda Centre for Research in Mental Health and Substance Use, The University of Sydney, Sydney, NSW, Australia. The Health4Me Study is funded by the Australian Government Department of Health Medical Research Future Fund Primary Care Grant (2006315). The funder has no role in this study's design; collection, analysis, and interpretation of data; or writing of this paper. RR is funded by a SOLVE-CHD Completion Scholarship. ART is funded by a University of Sydney Postgraduate Research Scholarship in Adolescent Health and Nutrition. JR is supported by an NHMRC Investigator Grant (Leadership Level 2 [GNT1143538]). SRP is supported by a National Heart Foundation Future Leader Fellowship (106646) and University of Sydney Horizon Fellowship.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to ethical approvals that protect the data of participants who have taken part in the study.

Authors' Contributions

RR, S Maguire, KW, S Mihrshahi, MLH, JR, SRP, and The Health4Me Team conceptualized the study. RR, ART, S Barakat, SR and S Boulet conducted the investigation. RR conducted the formal analysis and wrote the initial draft. JR and SRP provided supervision. All authors reviewed and edited this paper. All authors approved the final version of this paper.

Conflicts of Interest

None declared.

Abstract

Background: The severity of neonatal abstinence syndrome (NAS) may be assessed with the Finnegan score (FS). Since the FS is laborious and subjective, alternative ways of assessment may improve quality of care.

Objective: In this pilot study, we examined associations between the FS and routine monitoring data obtained from the electronic health record system.

Methods: The study included 205 neonates with NAS after intrauterine (n=23) or postnatal opioid exposure (n=182). Routine monitoring data were analyzed at 60±10 minutes (t–1) and 120±10 minutes (t–2) before each FS assessment. Within each time period, the mean for each variable was calculated. Readings were also normalized to individual baseline data for each patient and parameter. Mixed effects models were used to assess the effect of different variables.

Results: Plots of vital parameters against the FS showed heavily scattered data. When controlling for several variables, the best-performing mixed effects model displayed significant effects of individual baseline-controlled mean heart rate (estimate 0.04, 95% CI 0.02 - 0.07) and arterial blood pressure (estimate 0.05, 95% CI 0.01 - 0.08) at t–1 with a goodness of fit (R^2_m) of 0.11.

Conclusions: Routine electronic data can be extracted and analyzed for their correlation with FS data. Mixed effects models show small but significant effects after normalizing vital parameters to individual baselines.

Introduction

When exposure to opioids ends, neonates may develop withdrawal symptoms [1]. Neonatal abstinence syndrome (NAS), also referred to as *neonatal opioid withdrawal syndrome*, can be subdivided into primary NAS due to prenatal opioid abuse by (or treatment of) the mother, and iatrogenic NAS (iNAS) when neonates are treated with opioids. Primary NAS may develop in more than 90% of infants after intrauterine opiate exposure [2]. Occurrence and severity vary interindividually and are influenced by several factors, such as prematurity [3], breastfeeding [4], and multisubstance exposure, which results in more severe symptoms and worse outcomes than exclusive exposure to a single substance [5]. Though primary NAS is typically understood as abstinence from opioids, neonates can also develop withdrawal symptoms after exposure to other substances or medication such as tobacco [6], alcohol [7], cocaine [8], selective serotonin reuptake inhibitors and other antidepressants [9], benzodiazepines [10], and a combination of opioids and other substances [5].

Many neonatal intensive care units monitor withdrawal symptoms using the Neonatal Narcotic Abstinence Scoring System, also called the *Finnegan score* (FS), which is composed of 32 clinical signs, each scored between 0 and 5 (maximum score 46) [11]. The FS was originally designed to assess withdrawal in otherwise healthy-term infants from mothers abusing opioids [11,12]. Thus, the validity of the FS in other patients receiving neonatal intensive care is unclear, particularly in preterm or term neonates experiencing iNAS [11,12].

The implementation of electronic patient data management systems (PDMSs) alongside the availability of digital data on vital signs allows using data science algorithms to reevaluate clinical scoring systems and to facilitate clinical decision-making using decision support algorithms [13]. Having provided the first examples in adult medicine, these methods have shown promising results in neonatology. For instance, algorithmic analysis of heart rate characteristics is used to generate the Heart Rate Observation score—an estimate of the risk of developing sepsis [14]. Other approaches for early detection of sepsis use more variables and extensive machine learning algorithms but have not yet been validated in prospective settings [15]. Other studies have attempted to use data science algorithms to predict neonatal mortality [16]. Regarding opioid exposure, the PoPPI (Procedural Pain in Premature Infants) trial assessed the possibility of minimizing procedural pain in neonates receiving morphine treatment [17]. These data have allowed for the successful establishment of models predicting whether cardiorespiratory instability occurs after morphine administration and whether it requires intensified treatment [17,18].

Considering the subjectivity and the effort in generating an FS, the exploration of data-driven alternative ways of monitoring withdrawal symptoms appears necessary. In this pilot trial, we analyzed the association between electronic health data—mostly continuously and routinely monitored vital parameters—and the FS as a measure of the severity of NAS. Strong associations would allow an objective and less laborious NAS assessment based on routinely available data.

Methods

Ethical Considerations

The institutional review board of the Charité – Universitätsmedizin Berlin approved the study (EA2/104/21). Due to the retrospective nature of the study, the need for patient consent was waived.

Data Export and Inclusion and Exclusion Criteria

Continuously and routinely monitored vital parameters were extracted from the electronic health systems and harmonized for further analysis.

Data were exported for all patients admitted to the clinic between January 1, 2013, and February 1, 2022. The data set was then refined on the basis of the following inclusion criteria, and all calculations were later performed within the refined data set. To include all patients with continued clinical suspicions of withdrawal symptoms but to exclude those with one-time-only suspicions or accidental documentation, we performed the export by selecting patients with at least 3 documented FSs, since a pharmaceutical intervention was usually not initiated on the basis of a single scoring result. We cross-referenced this export selection with patients classified as having NAS in accordance with *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) criteria for quality control purposes. We categorized patients into subgroups of primary NAS and iNAS based on opioid medication, history of surgery, and time after birth before documenting the first FS for each patient. Primary NAS was coded when at least 1 FS was documented before any opioid medication was administered, any surgery was performed, and the patient had not yet approached postpartum day 8. iNAS was coded when any opioid medication was administered before the patient's first FS regardless of postnatal age. Patients with documented FS who did not meet any of these criteria were excluded. To design a sensitivity analysis, the analytic code was also applied to total study population without exclusion due to unclear NAS classification.

Review of Hospital Data Structure

Each variable was checked for availability within the hospital information system (SAP/Cerner) as well as the PDMS (COPRA) used in the neonatal wards (levels 1 ‐ 3).

Medication Data

Medications were not named consistently; hence, their names had to be preprocessed manually. We exported all unique medication entries from the PDMS and categorized them manually. The complete list of medication categories is provided in Multimedia Appendix 1.

Variables

To evaluate patients' demographics, we recorded their sex, gestational age at birth, birth weight, mode of delivery, number of documented FSs, and whether a time frame for individual baseline calculation was available and, if so, whether data were available within this time frame for the abovementioned vital parameters (including heart rate, respiratory rate, peripheral oxygen saturation, and mean blood pressure).

We calculated means for all variables listed below within specified time periods (t–1 and t–2, see the *Time Periods* section): heart rate, respiratory rate, peripheral oxygen saturation, and blood pressure.

Additionally, we generated an individual baseline for each patient by calculating the mean for each variable in a period of up to 5 days before documenting the first FS, which we defined as the relevant beginning of withdrawal (Figure 1). When calculating the individual baseline, we excluded spacer periods immediately post partum to minimize effects from postnatal adaptation and those immediately before documenting the first FS to minimize the effects of early-onset withdrawal. We set this spacer period to 1 day for patients with primary NAS and 3 days for those with iNAS (Figure 2). The sensitivity analysis was carried out with both spacer periods for the whole collective. We introduced the difference between this individual baseline and the mean of the respective vital parameter within the specified period before documenting any FS as a new variable to use as an alternative to the mean of the vital parameters and henceforth referred to this variable as the "baseline-controlled mean" (Figures 1 and 2).

Figure 1. Schematic representation of the calculation of an individual baseline-controlled mean of a given vital parameter—heart rate. To reduce the scattering of data in (**A**), we calculated the mean of the vital parameter for each patient (denoted with a green triangle, a blue dot, and a gray square) during the individual baseline period (**B**). The definition of this period is illustrated in Figure 2. We then calculated the difference from the baseline for each vital parameter of each patient, as shown in (**C**). When plotting this difference (**D**), we obtained individual baseline-controlled means for vital parameters plotted on a scale around zero and with a more linear grouping of all measurements, irrespective of patient identity.

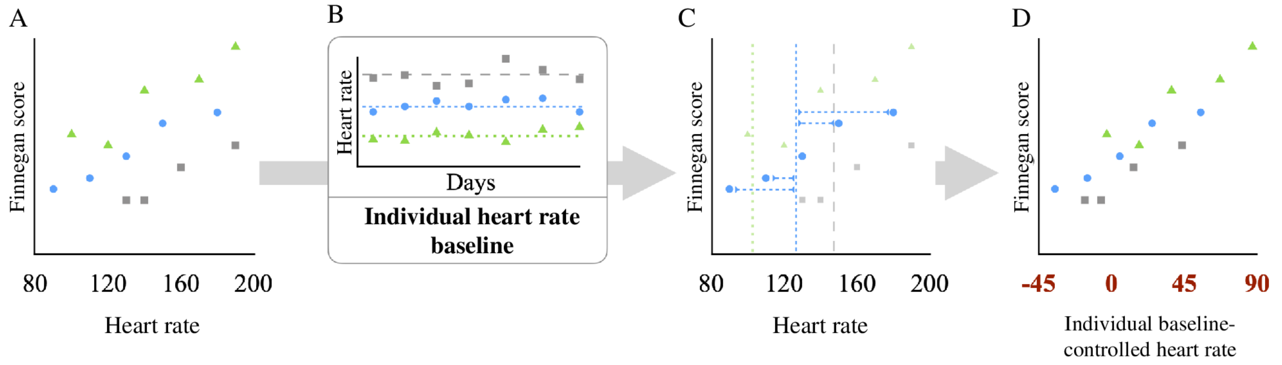

Figure 2. Time periods for the calculation of individual baselines (timeline not to scale). We defined a period to calculate an individual baseline for each patient of up to 5 consecutive days. After birth and before documenting the first Finnegan score, we introduced a spacer. [a]The spacer has a length of 1 day for patients with primary neonatal abstinence syndrome (NAS) and 3 days for those with iatrogenic NAS. [b]For all measurements within this period, we calculated a mean that is used to baseline-control measurements during every t–1 and t–2 for the respective patient; this baseline-control approach is illustrated in Figure 1.

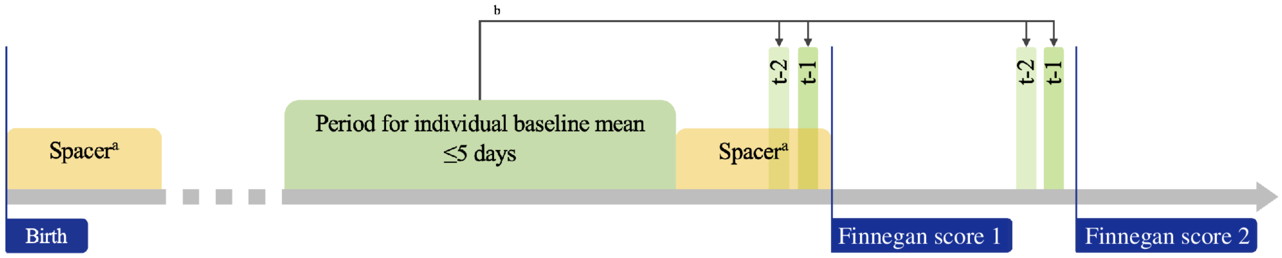

Body temperature was assessed in variable patterns, and we calculated the mean and baseline-controlled mean body temperature within 1 day before documenting each FS and used these data for both time periods (t–1 and t–2).

Furthermore, we included the following variables. (1) The pharmacodynamics of buprenorphine—the first-line pharmacotherapy for NAS—is highly complex, and data on transferability to neonates are limited [19,20]. Hence, we did not attempt to estimate pharmacodynamics in neonates but considered the time between the last documented opioid medication and each FS instead. As these *hours since medication* can only be recorded for patients who have been administered any opioids before documenting the respective FS, either because of iNAS or because of treatment of any type of NAS, we used the date of birth as the date of the last opioid medication for infants with primary NAS if no opioid medication was documented more recently. (2) The last body weight measure before documenting each FS was considered as a percentage of the individual's birth weight. (3) The current gestational age at each FS documentation was recorded.

Time Periods

All graphs and models were created for 2 time periods. With the goal of exploring options for predicting withdrawal symptoms, we focused on time periods before each FS. The first time period, t–1, was set to 1 hour±10 minutes before each FS, resulting in a 20-minute period from 10 minutes before until 10 minutes after the time point of 1 hour prior of each FS documentation. The second time period was set in the same manner to 2 hours±10 minutes before the respective FS, resulting in an earlier time period, t–2. The time periods are visualized in Figure 2.

Data Analysis Software

Data analysis was carried out using RStudio (version 2022.07.1+554) and R (version 4.2.1; 2022-06-23 ucrt) [21,22] using the following packages and their dependencies in addition to the function included in R, RStudio, and the ::base-package R during data extraction and harmonization: cli [23], data.table [24], dplyr [25], lubridate [26], tibble [27], and tidyverse [28].

We used the consort package to generate Figure 3 [29]. Table 1 was created using the tableone package; significance was tested using chi-square tests for categorical variables, Wilcoxon tests for skewed variables and *t* tests for normally distributed metric variables [30]. Skewness was assessed using the summary-function from tableone in accordance with tableone documentation [30]. We generated graphs with ggplot2 [31] and fitted our mixed effects models using lme4 [32]. Goodness of fit parameters of the mixed effects models was calculated using MuMIn [33]. Table output from RStudio was facilitated using flextable [34]. All code is has been published previously [35].

[a] All values rounded to integers except for pH.

[b] NAS: neonatal abstinence syndrome.

[c] N/A: not applicable.

[d] Categorial variables were assessed using the chi-square-test.

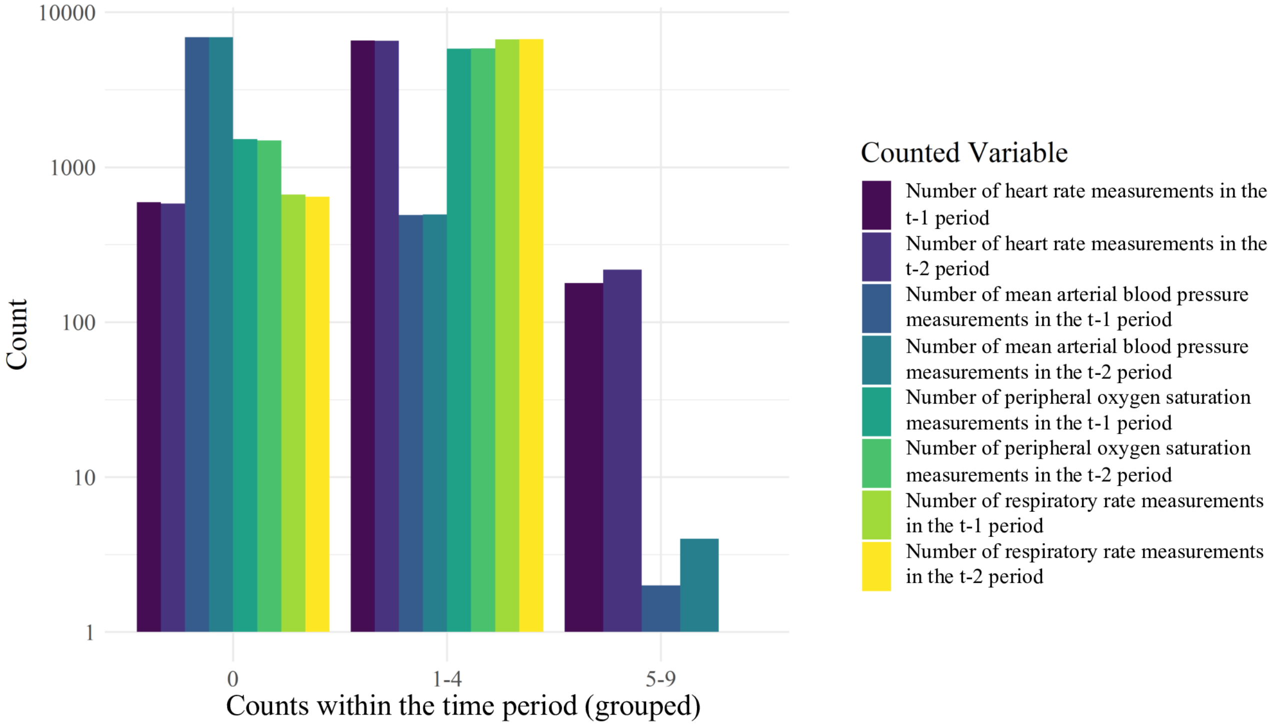
[e] Metric variables were assessed using the Wilcoxon–Mann-Whitney *U* test.

[f] Number of patients, for which a time interval for individual baseline calculation was definable but no data for the respective vital parameters were available within this interval.

Graphs

We visualized data availability in a clustered bar plot, reporting the number of data points per variable available for each patient within each period (Figure 4). By computing 2 statistical measures for each of the 4 vital parameter variables in each of the 2 time periods, we obtained a total of 16 graphs (see Multimedia Appendix 1). To visualize data distribution, we generated heat map plots. The color of each tile is set by the number of data points weighted by the number of measurements generating the data point so that data points based on more observations contribute more to the color scale. Hence, 2 data points based on 1 observation each and 1 data point based on 2 observations both result in the same color of the respective tile.

Figure 4. Distribution of data frequency within the time periods per variable. The y-axis is scaled logarithmically; the x-axis shows the groups of frequencies, starting with 0, corresponding to Finnegan scores for which there are no data points for the respective variables within the respective time period. All variables show counts within clusters 0 and 1 - 4. Within clusters 5 - 9, only counts for heart rate and blood pressure are available in both time periods.



Mixed Effects Models

We developed several mixed effects models. The models were fitted to descriptively analyze the relationship between the FS and vital parameters as well as NAS type, the time elapsed since the last opioid medication, gestational age, and the percentage of birth weight reached by the most recent body weight measurement. We controlled for interindividual differences by including the patient identifier as the random effect. We generally selected one set of vital parameter variables mixing neither means or individual baseline-controlled means nor the time periods of different vital parameters within a single mixed effects model. The models were not fitted to predict the FS; therefore, neither cross-validation nor bootstrapping were applicable. The regression equation for the full model was as follows, where “mean” could be substituted with “baseline-controlled mean” and “t–1” with “t–2” throughout the equation:

> *Value of Finnegan-Score~Intercept + Mean heart rate in the t–1 period + Mean peripheral oxygen saturation in the t–1 period + Mean respiratory rate in the t–1 period + Mean of the mean arterial blood pressure in the t–1 period + Mean body temperature within 1 day before documenting the FS + Hours between the last medication as specified and documentation of the FS + Percentage of birth weight + Gestational age + NAS type + (1 / patient identifier)*

We evaluated the goodness of fit again for models with a simplified set of variables, excluding variables with small effects (estimates of <0.05) and high degree of missingness (>30% missing values). Goodness of fit was determined using the Akaike information criteria (AIC), Bayesian information criteria (BIC), and R^2_m and R^2_c and is listed in Multimedia Appendix 1.

For the sensitivity analysis, we excluded the NAS-type variable from the full model. The model’s results and goodness-of-fit data from the sensitivity analysis can be found in Multimedia Appendix 2.

Results

Patient Characteristics and Data Composition

Patient demographic data are provided in Table 1, and patient allocation is demonstrated in Figure 3. Out of 205 neonates with NAS, 78 (38%) had been *ICD-10*–coded. Abstinence after intrauterine exposure (P96.1) was coded in 17.4% (n=4) of patients who were classified as having primary NAS and 5.5% (n=10) of patients who were classified as having iNAS. Abstinence after therapeutic exposition (P96.2) was coded in 21.7% (n=5) and 34.6% (n=63) of the respective patient groups. We obtained 7050 FS data points and calculated the baseline-controlled mean for up to 166 (81%) infants (Table 1). Two reasons prevented us from doing so in the other cases: no definable time period (as illustrated in Figure 2) or no data points within the time period to calculate upon.

Visual Interpretation

As shown in Figure 4, heart rate measurements showed the highest data density and mean blood pressure measurements showed the lowest. Heart rate measurements were the only variable for which at least 5 data points within a time period were commonly available, the only other variable being mean arterial blood pressure in very rare instances.

The plots show a widely distributed pattern for mean and baseline-controlled mean heart rate (Figure 5) and mean arterial blood pressure (Figure 6), each plotted against the FS. The tile color and different ranges shown in the color legends illustrate differences in the density of data available for heart rate and mean arterial blood pressure measurements; this corresponds to the data density described above and is shown in Figure 4.

While there was no direct relationship between the FS and the respective parameters visible, the graphs for the baseline-controlled version of each parameter showed a narrower spectrum on the x-axis. In particular, the baseline-controlled blood pressure shows a discernible trend of greater-than-zero values, indicating a rise in blood pressure in neonates in comparison with that before withdrawal assessment. However, this rise in baseline-controlled blood pressure does not clearly increase with an increase in the FS.

Figure 5. Heat maps of mean heart rate and baseline-controlled mean difference in heart rate during the t–1 time period (60±10 minutes before documenting the Finnegan score [FS]), values of children with iatrogenic neonatal abstinence syndrome. Left: the x-axis shows the mean heart rate in beats per minute (bpm); right: the x-axis shows the baseline-controlled mean difference in heart rate in bpm. Each tile has a width of 2 bpm and a height of 1 FS point; the opacity is generated from the amount of data points within the area of the respective tile weighted by the number of heart rate observations that each of those data points is calculated from.

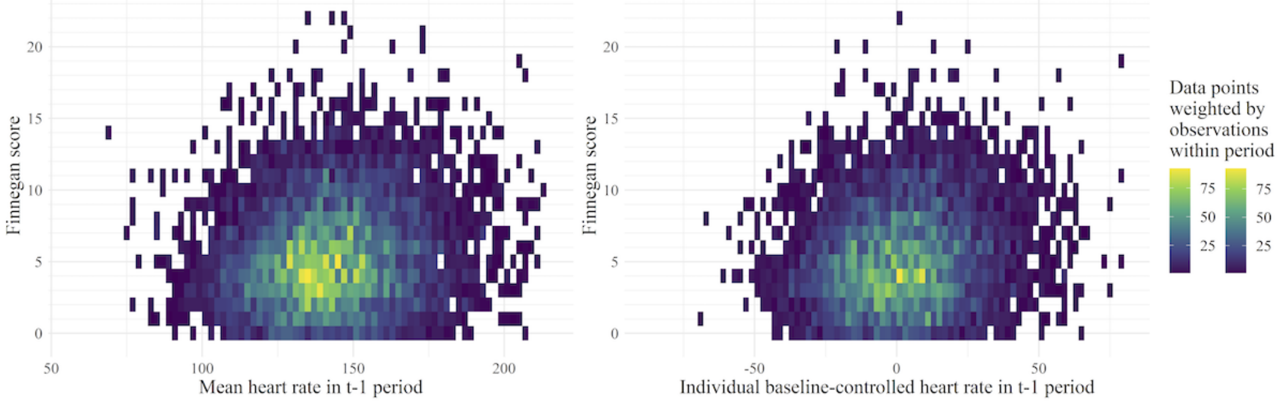


Figure 6. Heat maps of mean and baseline-controlled mean arterial blood pressure during the t–1 period (60±10 minutes before documenting the Finnegan score [FS]) for children with iatrogenic neonatal abstinence syndrome. Left: the x-axis shows the mean arterial blood pressure in mm Hg; right: the x-axis shows the baseline-controlled mean arterial blood pressure in mm Hg. Each tile has a width of 2 mm Hg and a height of 1 FS point; the opacity is generated from the amount of data points within the area of the respective tile weighted by the number of mean arterial blood pressure observations that each of those data points is calculated from.

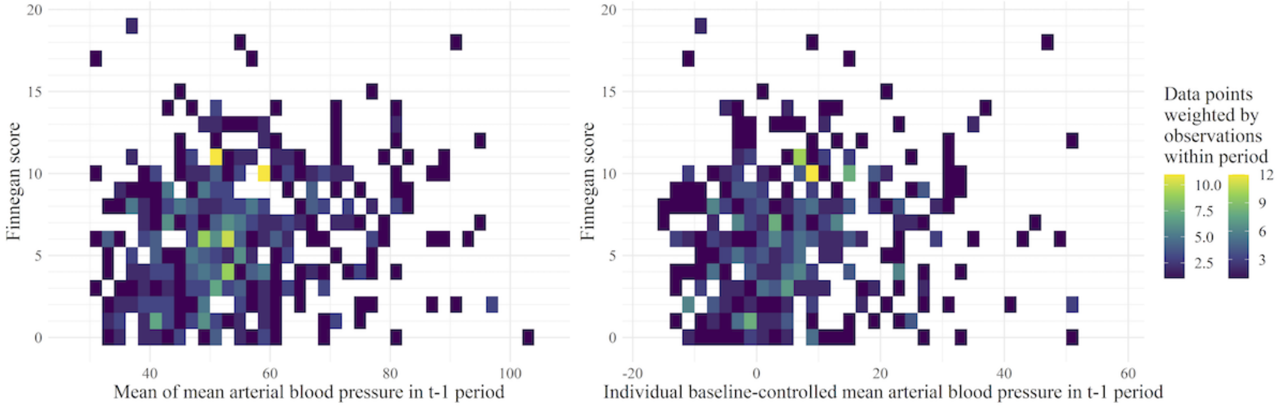

Regression Analysis of Vital Parameters in Fitted Models

Estimates for vital parameters stayed either positive or negative across all fitted models and varied only in the corresponding SEs, CIs, and *P* values. Among all models, the model containing all variables, using the later time period of t–1 and the baseline-controlled mean as the statistical measure, yielded the highest R^2_c and R^2_m and second-lowest AIC and BIC (Table 2). This model was fitted on 357 observations obtained from 84 infants.

Table . Results of the mixed model using baseline-controlled means as statistical measures, t–1 as time period, and a complete set of variables (R^2_m=0.11; R^2_c=0.43; Akaike information criterion=1999.36; Bayesian information criterion=2045.89; 84 patients; 357 Finnegan scores).

Parameters	Estimate	SE	95% CI	*P* value
(Intercept)	9.31	2.88	3.51 to 14.92	.002
Individual baseline-controlled heart rate in the t–1 period	0.04	0.01	0.02 to 0.07	<.001
Individual baseline-controlled peripheral oxygen saturation in the t–1 period	–0.09	0.05	–0.19 to 0.01	.09
Individual baseline-controlled respiratory rate in the t–1 period	0.00	0.01	–0.02 to 0.03	.84
Individual baseline-controlled mean arterial blood pressure in the t–1 period	0.05	0.02	0.01 to 0.08	.005
Individual baseline-controlled body temperature within 1 day before documenting the Finnegan score	0.33	0.49	–0.63 to 1.28	.51
Hours between last medication as specified and Finnegan score	0.00	0.00	0.00 to 0.00	.46
Percentage of birth weight	0.00	0.00	–0.01 to 0.00	.19
Gestational age	–0.06	0.06	–0.18, to 0.06	.35
Iatrogenic (vs primary) neonatal abstinence syndrome	–0.27	1.64	–3.41 to 2.92	.87

An increasing individual baseline-controlled heart rate (estimate 0.04, 95% CI 0.02 to 0.07) and an increasing arterial blood pressure (estimate 0.05, 95% CI 0.01-0.08) correlated significantly with an increased FS.

Furthermore, a decreasing individual baseline-controlled peripheral oxygen saturation (estimate –0.09, 95% CI −0.19 to 0.01), decreasing gestational age (estimate −0.06, 95% CI −0.18 to 0.06) as well as increasing individual baseline-controlled respiratory rate (estimate 0.00, 95% CI −0.02 to 0.03), increasing hours since the last medication (estimate 0.00, 95% CI 0.00-0.00), increasing baseline-controlled body temperature (estimate 0.33, 95% CI −0.63 to 1.28), increasing percentage of birth weight (estimate 0.00, 95% CI −0.01 to 0.00), and the status of iatrogenic (vs primary) NAS (estimate −0.27, 95% CI −3.41 to 2.92) were associated with an increasing FS. However, while the inclusion of these variables improved the goodness of fit of the model, the estimates showed SEs and 95% CIs too large to be considered significant.

The irregularity and scarcity of blood pressure measurements in neonatal standard care resulted in missing values for the individual baseline-controlled mean arterial blood pressure and thereby reduced the amount of complete data on which the model could be fitted. Due to the large number of missing values (mean blood pressure unavailable for >90% of FS), imputation was not applicable. When blood pressure was not included—thereby reducing the complexity of the model but increasing the number of complete observations—all measures for goodness of fit decreased (worst model with blood pressure [R^2_m=0.08, AIC=2345]; best model without blood pressure [R^2_m=0.07, AIC=25,992]). On excluding the NAS type from our sensitivity analysis, these results were confirmed. Including previously excluded patients and using spacer periods of the same length for all patients during baseline calculation resulted in similar results (Multimedia Appendix 2).

The abovementioned estimated effects are small and may seem clinically irrelevant. However, due to the nomenclature of mixed effects models, the estimates refer to 1-unit changes of the respective variable. This implies that a heart rate increase of 10 beats per minute from the individual baseline would coincide with an FS increase of 0.4 and a 10-mm Hg increase (increase of 0.6) in the mean arterial blood pressure assuming that all other values remained constant.

Discussion

This pilot study shows a measurable association between withdrawal assessment based on FS and heart rate and blood pressure, which underlies heavy scatter and is only revealed when controlling for several other influencing variables in regression analysis. The unfiltered correlation between FS values and vital parameters was weak, and the analysis revealed heavily scattered data. Thus, we fitted mixed effects models that corrected for various variables. These models supported the hypothesis that opioid withdrawal measured by FS is associated with vital parameter readings if big data sets are considered. Multiple analyses revealed robust estimates with a small magnitude for the association of increasing FS with an increased heart rate and arterial blood pressure (Table 2) but not with the respiratory rate. However, even in the model exhibiting the best goodness of fit (R^2_m=0.11; Table 2), this association was found to be weak, likely because of heavily scattered input data. Notably, our analysis only revealed an association with the FS, which, while being the currently and widely used assessment tool for withdrawal, can only be understood as a resemblance of the latter, not withdrawal itself.

The use of electronic monitoring data and health records may become an attractive source for clinical decision-making (eg, for identifying the risk of sepsis) or multivariable predictive models (eg, for neurodevelopmental impairment) in neonatology [36-39]. While more conservative models perform similarly on the task of predicting sepsis in neonates, advanced machine learning techniques exhibit better performance in case of heterogenous big data pipelines [40].

Conceptually, it is appealing to develop such a big data–based prediction strategy, particularly if it can be validated by using a clinical scoring system. Since opioid withdrawal symptoms considered in the FS rely on the accuracy of reporting, detecting, and describing symptoms, adding monitoring or laboratory data might improve subsequent clinical decisions. However, items in the FS may be too complex per se for fitting common models of analyzing big data from electronic health records. In this regard, the density of electronic monitoring data, such as arterial blood pressure, was surprisingly low in our cohort. Other easily accessible data such as intrauterine growth restriction and maternal tobacco or multisubstance abuse also failed to sufficiently predict NAS severity in previous studies [41]. Success in using continuously monitored electronic data for decision-making in care of neonatal opioid withdrawal, however, may critically depend on the granularity of these data. At our institution, the heart rate may have been recorded with very low data granularity, for example (Figure 4), as these readings were previously summarized to means for storage capacity reasons. This is not unusual as hospital systems regularly do not save the highest available data frequency to reduce the required data storage space, all the while limiting its use for research at later stages [40]. Thus, we applied specific periods (t–1 and t–2; Figures 1 and 2) and identified an individual baseline of vital parameters to compile data with varying temporal resolution. Of note, temporal cross-correlation of vital parameters might have resulted in an improvement in predictive values on the severity of FS, as previously shown in other cohorts of preterm infants with sepsis, necrotizing enterocolitis, or retinopathy [38,42,43].

To date, our data did not offer sufficient temporal resolution to cross-correlate vital parameter data strings. However, based on the most the recent study by Poppe et al [38], we suggest that continuously logged electronic data sampled preferentially at 1 Hz should be obtained. For model development, such high-frequency data may also be obtained during prospective trials. For model validation, real-world data are required at a later stage. High temporal resolution also allows models to reach high levels of goodness of fit and significance with the use of relatively basic sets of variables, as demonstrated for both instability and requirement of treatment after morphine analgesia based on documented episodes of apnea, profound oxygen desaturation, the average heart and respiratory rates, and the postmenstrual age [18]. While our models based on our limited temporal resolution data did not show significant effects of changes in the respiratory rate, the addition of respiratory signals to heart rate characteristics also improved the performance of sepsis prediction models. The resulting model features an especially strong negative predictive value, and we suggest validating this model with larger cohorts [44]. Further research is necessary to not only validate the effects we observed in other cohorts but also analyze associations between high-frequency data and withdrawal, potentially using measures obtainable within these data, such as heart rate characteristics and variations. Most recently, our institution has begun to archive vital parameter data in real time and with high resolution, enabling us to pursue this path.

Our data do not allow considering the different (substance or dose) pharmacologic interventions for neonatal opioid withdrawal and variations in the half-life of such substances when computing the time elapsed since the last administration and the next FS. The complex metabolism of buprenorphine in neonates [19,20] may also affect the analytical mixed models' performance and be relevant for strategies using artificial intelligence for future clinical decision-making.

Despite these limitations, the discrepancy between the FS and data from electronic monitoring may also reflect an inherent weakness of the clinical score. Since the FS has been reported to be subjective, resulting in low interrater reliability, our study indirectly supports the "Eat, Sleep, Console" approach for neonatal opioid withdrawal as successfully shown in the recent cluster-randomized controlled trial of the ACT NOW Collaborative [45].

Acknowledgments

Abstract

Background: After the implementation of 2- and 3-child policies, the rising proportion of high-age and high-risk pregnancies put enormous pressure on maternal and child health (MCH) services for China. This populous nation with an increasing population flow imperatively required the support of large-scale information systems for management. Municipal MCH information systems were commonly applied in developed cities of eastern provinces in China. However, implementation of provincial MCH information systems in relatively low-income areas is lacking. In 2020, the implementation of a regional maternal and child information system (RMCIS) in Inner Mongolia filled this gap.

Objective: This paper aimed to demonstrate the construction process and evaluate the implementation effect of an RMCIS in improving the regional MCH in Inner Mongolia.

Methods: We conducted a descriptive study for the implementation of an RMCIS in Inner Mongolia. Based on the role analysis and information reporting process, the system architecture design had 10 modules, supporting basic health care services, special case management, health support, and administration and supervision. Five-color management was applied for pregnancy risk stratification. We collected data on the construction cost, key characteristics of patients, and use count of the main services from January 1, 2020, to October 31, 2022, in Inner Mongolia. Descriptive analysis was used to demonstrate the implementation effects of the RMCIS.

Results: The construction and implementation of the RMCIS cost CNY 8 million (US $1.1 million), with a duration of 13 months. Between 2020 and 2022, the system recorded 221,772 registered pregnant women, with a 44.75% early pregnancy registry rate and 147,264 newborns, covering 278 hospitals and 225 community health care centers in 12 cities. Five-color management of high-risk pregnancies resulted in 76,975 (45.45%) pregnancies stratified as yellow (general risk), 36,627 (21.63%) as orange (relatively high risk), 156 (0.09%) as red (high risk), and 3888 (2.30%) as purple (infectious disease). A scarred uterus (n=28,159, 36.58%), BMI≥28 (n=14,164, 38.67%), aggressive placenta praevia (n=32, 20.51%), and viral hepatitis (n=1787, 45.96%) were the top factors of high-risk pregnancies (yellow, orange, red, and purple). In addition, 132,079 pregnancies, including 65,018 (49.23%) high-risk pregnancies, were registered in 2022 compared to 32,466 pregnancies, including 21,849 (67.30%) high-risk pregnancies, registered in 2020.

Conclusions: The implementation of an RMCIS in Inner Mongolia achieved the provincial MCH data interconnection for basic services and obtained both social and economic benefits, which could provide valuable experience to medical administration departments, practitioners, and medical informatics constructors worldwide.

information system; maternal and child health care; system construction; system implementation; regional health; Inner Mongolia Autonomous Region

Introduction

In the Sustainable Development Goals issued by the World Health Organization (WHO), the most concerning targets related to good health and well-being were a reduction in the maternal mortality rate (MMR), neonatal mortality rate (NMR), and under-5 mortality rate (UMR), with the purpose of maternal and child health (MCH) improvement [1]. MCH and related measures, such as family planning and immunization, comprise one of the foundation stones for public health [2].

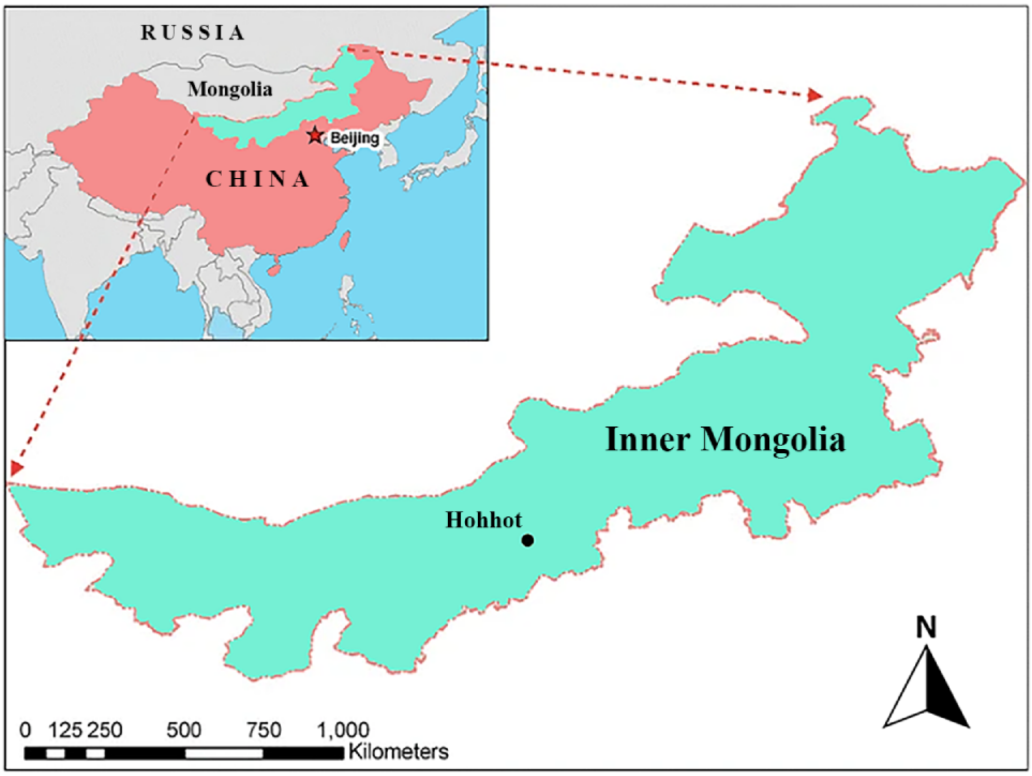
China has emphasized MCH as an essential component of China's health care system [3]. In October 2016, the Healthy China Action Plan (2019-2030) set clear requirements that the MMR and the NMR should be reduced to 12/100,000 and 5/1000 by 2030 [4]. In the past few years, the MMR of China has dropped from 23.2/100,000 in 2013 to 15.7/100,000 in 2022 [5,6]. After the implementation of the 2-child policy in 2016 [7] and the 3-child policy in 2021 [8], multiparous births exceeded primiparous births nationwide [9]. The rising proportion of high-age pregnancies (maternal age ≥35 years) resulted in a significant increase in pregnancy risks [9], putting enormous pressure on MCH services in China, with over 10 million newborns every year [6].

With the rapid development of medical informatization [10], the information construction for MCH has been a prominent development trend. Thanks to the similar gestation cycle and production inspection process, data types of MCH records are homogenous, which creates a positive precondition for the construction of a maternal and child information system (MCIS). In such cases, localized MCH informatization was launched worldwide. As early as in 1984, the Maternal and Child Health Information Network (MATCH) [11] was created to serve as a pilot project to manage data related to prenatal, child health, family planning, and genetic services in clinics in the state of Ohio in the United States. The South Western Sydney Area Health Service launched the Mother and Infant Network (MINET) in 1997 [12] in order to develop an integrated clinical data network to support a continuum of MCH care, including in-patient, ambulatory, and community-based services. However, all these systems were designed to be used only in a few clinics with limited features and served as a simple tool to record in-diagnosis information, leading to a relatively small application scope.

Given the disparity in economy and medical resources [13], China imperatively requires practical tools to integrate regional medical resources for MCH improvement, especially in low-income areas [14,15]. The increasing population flow with economic migration also demands higher-level resident information sharing in a wider scope [16]. However, although most medical institutions have already set up internal business systems, such as the hospital information system (HIS), the laboratory information system (LIS), and the imaging system, data noninteroperability has become a general problem [17], which poses difficulties for the construction of MCISs and the realization of full coverage of MCH services. In China, the initial attemps for MCISs started at the beginning of 21st century. The first version of the regional maternal and child information system (RMCIS) was implemented in the Xiamen Maternal and Child Health Hospital in 2003. In Shanghai, districts, such as Changning District in 2007 and Songjiang District in 2013, set up their own MCISs. Beijing established a citywide MCIS and a big data platform for MCH information in 2017. Prior interface and data standards for core functions were considered as common solutions to address the issues of data noninteroperability and ensure the realization of basic services. With the increasing requirements for geographical coverage, eastern provinces with high-income economies, such as Guangdong and Guangxi, took the lead in the construction of provincial MCISs. Conversly, due to the relatively poor economic development [18], implementation of provincial MCISs in western provinces is lacking. Challenges are significant because the relatively poor conditions are characterized by a weak economy, inconvenient transportation, a sparse population, and even insufficient medical resources, especially in rural and remote areas [19]. To address the imbalance issue and improve regional MCH services, Inner Mongolia, a western province in China, implemented a provincial RMCIS in 2020.

The Inner Mongolia Autonomous Region (hereafter referred to as Inner Mongolia) is an autonomous region of minorities located in north China, with 9 cities and 3 leagues. It covers 1.18 million square kilometers, with 12% of China's total land area and 24.05 million recorded residents (Figure 1) [20]. Due to the influence of the geographical location, a highly variable climate, and historical and cultural reasons, regional development disparity exists and the average economic development is behind that of eastern coastal regions in the country [21]. In 2021 and 2022, the gross regional product of Inner Mongolia ranked 21st among 34 provinces across the country [22]. This vast territory with a sparse population had a high demand for health service improvement, given the high turnover rate of medical workers in remote places and the limited access to tertiary hospitals for the residents. In such cases, a dense distribution of community health care centers is necessary for universal coverage health, which is the primary aim of the right care [23].

Figure 1. Geographical location map of Inner Mongolia (adapted from Xu et al [21], which is published under Creative Commons Attribution 4.0 International License [24]).



In recent years, Inner Mongolia has vigorously improved its MCH, focusing on the core task of prioritizing children and ensuring the safety of mothers. Before the implementation of the provincial RMCIS in 2020, two allied cities in Inner Mongolia, Wuhai in 2014 and Hohhot in 2017, constructed municipal MCISs for the purpose of MCH service management and data report. MCH outcomes were promoted, with the MMR decreasing from 20.64 to 9.92 for every 100,000 pregnant women and the NMR decreasing from 8.45 to 2.2 for every 1000 pregnant women from 2012 to 2021 [25]. During the 13th 5-year period (2016-2020), the MCH service capacity was also greatly enhanced. The rate of hospitalized deliveries for pregnant women continuously exceeded 99%, the systematic management rate of pregnancies rose from 93.77% to 94.68%, the systematic management rate of children under age 3 years rose from 92.82% to 94.72%, and the rate of screening for women's diseases rose from 68.84% to 82.73% [26]. Three-level preventive measures against birth defects were implemented, covering urban and rural residents. The maternal prenatal screening rate rose from 49.31% to 88.90%, the newborn disease screening rate rose from 65.04% to 96.86%, and the newborn hearing screening rate rose from 79.96% to 96.23% [26]. The medical service network was extended, maintaining 24,951 medical institutions in total, including 806 (3.23%) hospitals, 1251 (5.01%) community health care centers, 114 (0.46%) MCH hospitals, 1301 (5.21%) MCH and family planning service stations (township health centers), 13,000 (52.1%) village health offices, 15 (0.06%) maternity hospitals, and 2 (0.01%) children's hospitals [26]. In the 14th 5-year plan, Maternal and Child Health Care Development Plan for Inner Mongolia (2021-2025) [26], with the assistance of the RMCIS, a 5-level MCH service network is expected to cover the entire autonomous region, allied cities, flag counties (cities, districts), soum townships (streets), and gacha villages (communities).

In response to the increasing demand for large-scale service management and data report, the RMCIS would tremendously improve regional MCH with data interconnection. The implementation experience of the RMCIS in Inner Mongolia was a representative case in China, and even worldwide, which filled the gap of provincial MCISs in relatively low-income areas. This paper aimed to describe the construction process and evaluate the implementation effects of the RMCIS in improving provincial MCH in Inner Mongolia, which might provide helpful experience for the construction of RMCISs in other areas.

Methods

Role Analysis

The setup of an RMCIS covers extensive MCH services provided in all MCH service institutions. The regional MCH service network usually consists of community health care centers (stations), township health centers, village health clinics (rooms), MCH hospitals, midwifery institutions, child care institutions, and hospitals. In fact, the medical institutions also have the responsibility for other non-MCH–related services, but the design of the RMCIS only focused on MCH services. The collected MCH data are reported to health administration departments. Due to the complex relationships between MCH services and institutions, service role analysis was crucial at the initial stage of establishment.

According to the National Health Commission (NHC) [27], medical institutions can play 7 specific roles in the regional health care system. Due to the particularities of medical institutions' functional settings, 13 types of institutions were involved in MCH information interworking. The features included in each module for different institutions were clearly set. Furthermore, specific authorizations of different institutions were required for the privacy protection of public health and patients. The role analysis of the MCH service and medical institutions was presupposed in the Technical Program for Construction of Regional Maternal and Child Health Information System (Table 1).

MCH service roles are classified into basic MCH services and administrative management. Basic health care services include most of the tabulated features and thus relate to the majority of medical institutions. Especially, community health care centers in the communities and health stations in the township take the responsibility of all basic services, which are the cornerstones for the hierarchical diagnosis and treatment system implemented in the country. The RMCIS integrates regional MCH resources and provides intelligent and intuitive tools for health administration departments, medical institutions, and patients. The RMCIS covers medical institutions from community health care centers to township hospitals to municipal hospitals and provides functions including high-risk intelligent assessment, automatic identification of high-risk children, self-collection of outpatient physical signs, and performance appraisal.

Business Architecture Design

The RMCIS renders continuous services for the entire MCH process. Health care service management is a closed-loop system, which means all actions and records from prediagnosis to in-diagnosis to postevent are traceable, ensuring system-wise efficiency, security, and quality.

A standard pregnancy care process protocol was set up by the NHC, according to the Pregnancy and Childbirth Health Care Work Administrative Regulation and the Pregnancy and Childbirth Health Care Work Principles [28] of 2011. To protect pregnant women's rights stipulated in the Maternal and Child Health Law of the People's Republic of China [29], the whole process of pregnancy and childbirth care was divided into 4 consecutive steps: preconception care, antenatal care, intrapartum care, and postnatal follow-up.

Preconception care mainly refers to a series of health services for a couple preparing for pregnancy, including health education and consultation, preconception medical examinations, health status assessment, and guidance.

Antenatal care is launched between the conception confirmation and the delivery, referring to health education and consultation, antenatal medical examinations, general examinations, obstetric examinations, and ancillary examinations (ie, basic examinations and recommended examinations). The regulation requires that every pregnant woman receive at least 5 antenatal visits: 1 first visit and at least 4 revisits. If conception is confirmed using ultrasonography, the pregnant woman is registered and managed in the system and receives a copy of the *Maternal and Child Health Handbook* (MCHH) developed by the Japan International Cooperation Agency originally in 1948 [30].

The frequencies of antenatal visits differ in every trimester. During the first trimester (ie, before the 13th gestational week) and the second trimester (ie, from the 13th to the 27th gestational week), pregnant women only receive antenatal care every 4 weeks, while in the third trimester (ie, after the 28th gestational week), the frequency reduces to 1 or 2 weeks. Each pregnant woman undergoes necessary basic and optionally recommended examinations, depending on her specific pregnancy conditions during antenatal care.

Five-color management for pregnancy risks was proposed by the Department of Maternal and Child Health of the NHC [31]. Pregnant women are classified into 5 levels of pregnancy risk using colors: green (low risk), yellow (general risk), orange (relatively high risk), red (high risk), and purple (infectious disease), as shown in Table 2. Pregnant women without risks are recommended to get registered and obtain a copy of the MCHH for recording in community health care centers in the first trimester, which is considered an early filing rate and is used during the performance appraisal of those centers. After the 21st gestational week of pregnancy, women who have never completed any maternity checkups in community health care centers should get registered in hospitals to undergo a proper medical examination. However, if a woman's pregnancy risk is high (ie, yellow, orange, red, or purple), arrangements will be made in a tertiary hospital even before the 21st gestational week. Regarding delivery, pregnant women are suggested to make an appointment for a bed in the first trimester (before the 14th gestational week) in a community health care center, but only hospitals are qualified to help them give birth.

Table 2. Risk levels and types in 5-color pregnancy risk management.

Risk color	Risk level	Risk types
Green	Low risk	No pregnancy complications
Yellow	General risk	Age≥35 or ≤18 years, genital malformation, pelvic stenosis, etc
Orange	Relatively high risk	Age≥40 years, severe preeclampsia, severe anemia, etc
Red	High risk	Dangerous placenta previa, placental abruption, severe anemia, etc
Purple	Infectious disease	Viral hepatitis, syphilis, AIDS, etc

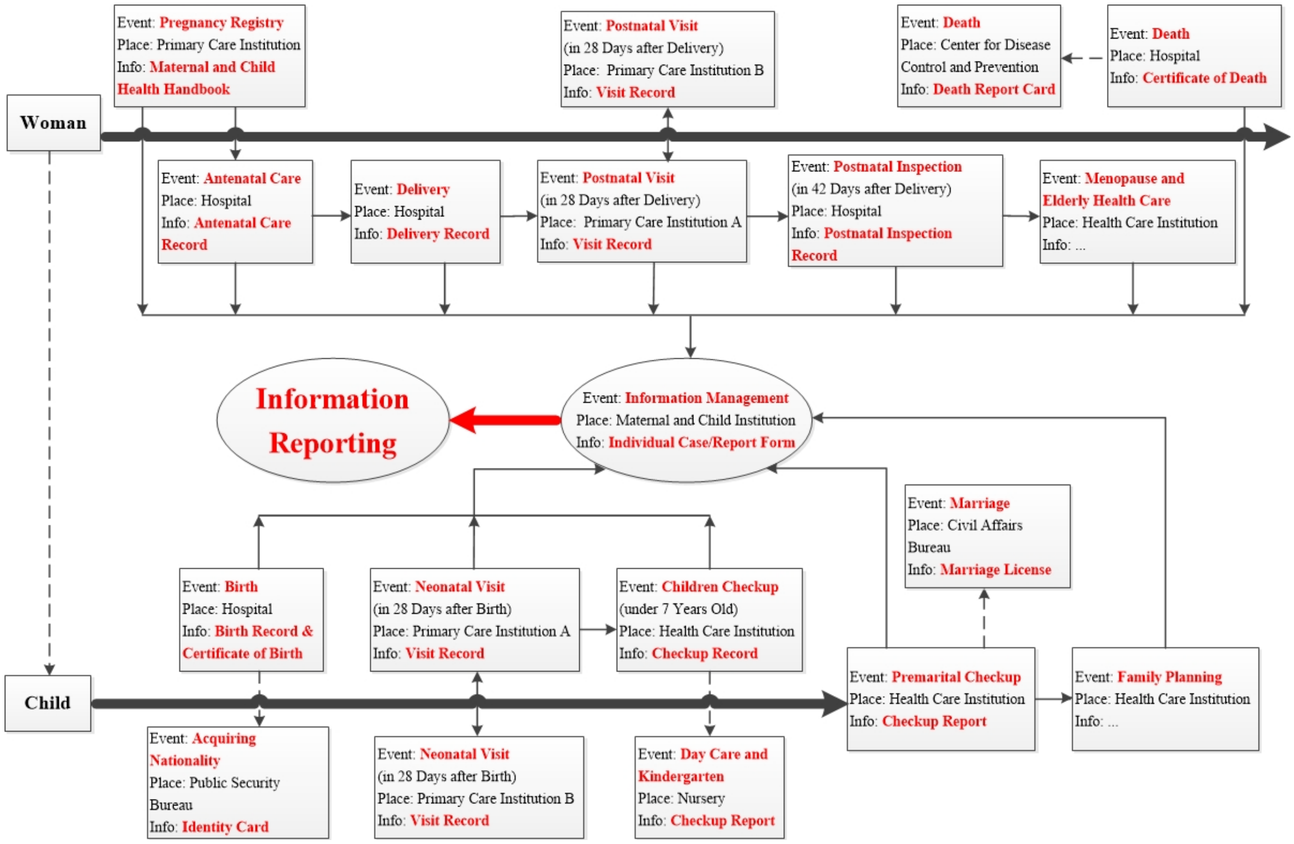
Intrapartum care refers to a process of comprehensive and dynamic assessment of maternal health, monitoring of mother and fetus, and prevention and treatment of complications during labor and delivery.

After delivery, the postnatal follow-up includes health care during hospitalization, postnatal visits for the mother and the newborn, and postnatal checks. Primary care workers offer 2 visits, one within 3-7 days and the other within 28 days after delivery. The postnatal check for mothers should be performed in a qualified maternity institution 42 days after delivery.

Following the whole preconception care, childhood follow-ups for newborns are conducted in the 1st, 3rd, 6th, 8th, 12th, 18th, 24th, and 36th months during the first 3 years. Later, follow-ups are conducted annually by kindergartens until the child becomes 6 years old.

The information reporting process of the RMCIS was designed according to the aforementioned closed-loop process. In addition to pregnancy and childbirth care, other maternal care services, such as premarital checkup, family planning, cervical cancer and breast cancer (CC and BC) screening, and childhood follow-up, are also included in this system. Every event occurs in the way of individual information forms created in the system. Based on the role analysis, each event takes place in a different medical institution, but all the data are uploaded to the same information system. In addition, the RMCIS is linked to other health data systems, such as public security bureaus, ensuring that vital statistics data, such as birth and death certificates, are accurately collected (Figure 2).

Figure 2. Business architecture design for the information reporting process.



Functional Modules and Services

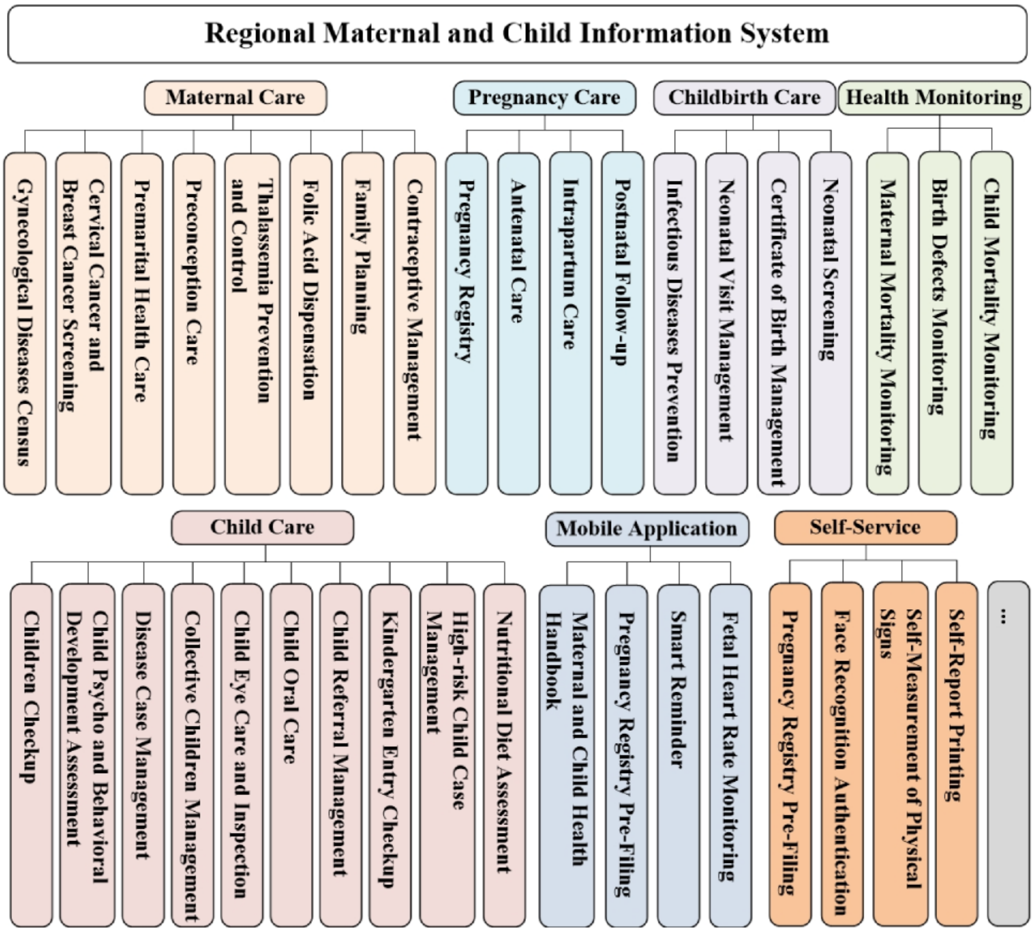
The essence of an RMCIS is to achieve data interconnection between medical institutions and provide coherent services for the whole health care process based on standardization. Core services were classified into 4 dimensions: basic health care services, special case management, health support, and administration and supervision. Compared to the basic health care services, which are the foundation for medical institutions and cover the whole life cycle of patients, other intelligent supplementary features of pregnancy and childbirth care, such as pregnancy risk surveillance and special case management of high-risk children, guarantee that patients with different medical needs receive proper treatments. Policy making and clinical decision support help medical workers comprehend the health status of patients and accordingly provide prescriptions. Databases for special cases, such as maternal anemia, weight gain during pregnancy, and high-risk newborns, are also built based on this system.

The RMCIS provides health support to users with self-service, but it still has great potential for development. The broadest application of self-service is pregnancy registry prefiling, which reduces the repetitive work of medical workers and ensures the authenticity of patients' personal information. Patients can fill their personal information in the prefilling forms through mobile apps or official WeChat accounts and conveniently complete pregnancy registry later in community health care centers. Common features (eg, health encyclopedia, daily service information and policies, automatic reminders, medical records, and examination result queries) and extensive services (eg, nutrition assessment, psychological assessment) have also been added to the mobile apps. In addition, daily personalized pregnancy knowledge and appointment reminders can be set in official WeChat accounts. Thanks to the telemedicine services provided by online hospitals, patients can further initiate interactive communications with health care experts online. Finally, the latest technologies, such as the internet of things (IoT), allow remote fetal heart monitoring to be applied broadly, even during an epidemic.

As mentioned in the *Role Analysis* section, most administration and supervision functions are directed to administrative departments, such as the NHC. The administrative departments can then extract data and display MCH surveillance indicators (maternal mortality and child mortality under age 5 years and neonatal birth defect surveillance) through queries. In this way, comprehensive statistics based on MCH can be easily gathered, contributing to period report writing. However, for administrative departments in medical institutions, special case management and supervision are crucial for the treatment of high-risk patients, while performance appraisal is a tool to assess medical workers.

Based on 4 core dimensions (basic health care services, special case management, health support, and administration and supervision), 10 modules were set up in the system: (1) maternal care, (2) pregnancy care, (3) childbirth care, and (4) child care for basic health care services; (5) mobile app and (6) self-service for health support; (7) health monitoring, (8) system management, (9) data center, and (10) other for the health administration department and the maintenance team. The maternal care module covers most of the services except pregnancy and childbirth care (which is divided into antenatal care and neonatal care), while the child care module only includes childhood follow-up services (Figure 3).

Figure 3. Functional module diagram for the regional maternal and child information system (RMCIS).



Intelligent Health Management and Decision Support

As concrete health care services can be divided into specific modules, intelligent health management and decision support are embedded in every feature of the RMCIS to assist medical workers with reasonable prescriptions. These intelligent services using new techniques make the RMCIS distinct from a simple information system.

The RMCIS can identify and assess the risk of a pregnant women based on her physical signs, report results, and *International Classification of Diseases, Tenth Revision* [32] diagnosis. Subsequently, the system estimates the pregnancy risk level and automatically implements 5-color management. Normal or low-risk pregnant women are further distinguished from high-risk patients by gestational diabetes, hypothyroidism, iron deficiency anemia, twin pregnancies, preeclampsia, etc, so that the system can make an intelligent diagnosis more precisely. Since the management of each patient is a closed-loop system, doctors can easily look up previous maternity checkup results according to the timelines and make a diagnosis with the help of the RMCIS. For high-risk pregnant women, the RMCIS reminds doctors and patients to carry out special case management and track on a regular basis.

The RMCIS also assesses children's growth status according to the measured data and alerts whether a child has a high-risk growth problem (wasting, obesity, anemia, etc). The system is interfaced with other in-hospital systems to extract data of physical signs and laboratory results, automatically calculates the child's growth and development status, and draws a WHO standard growth monitoring chart to assess the development level. In this manner, doctors can intuitively observe the child's growth status and give reasonable advice with intelligent health management guidance from the RMCIS. Special cases are highlighted in the system according to WHO and 9 Chinese provincial and municipal standards, effectively reducing deaths caused by untimely detection or resuscitation of high-risk diseases.

Furthermore, the traditional outpatient physical sign collection equipment has been transformed to an automatic one with the IoT technique. For instance, the automatic electronic blood pressure meter can be highly interconnected with intelligent equipment and an HIS, which can automatically upload blood pressure data to the system. It can also automatically fill in the patient's physical signs form, without manual entry, and thus simplifies the maternity checkup process. In addition, the remote fetal heart rate monitoring services have been extended to communities and families, closing the gap in out-of-hospital monitoring. Pregnant women can carry out fetal heart monitoring at home according to doctors' advice and upload the real-time monitoring data through their mobile phones. Hence, nursery stations can immediately uncover emergency conditions.

Technical Design

In the system design, feasibility, flexibility, robustness and scalability, and maintenance were considered as the basic design principles of system integration [33]. With reference to the guidelines of the NHC [34,35], the RMCIS was designed and constructed to achieve the whole life cycle management of MCH services for residents.

The RMCIS was deployed at a specialized network, while mobile services were deployed on the internet. Logical isolation separated the internet from the specialized network through firewalls and bastions. The system has realized docking with HISs, citizens' health platforms, management systems of primary health care institutions, and other systems, standardizing the management of MCH services in covered medical institutions and realizing the sharing and exchange of MCH resources. Large distributed databases, such as ORACLE (recommended for expandability and compatibility) and SQLServer, were supported, and centralized storage was adopted, with the builder providing the database server and specifying the storage location. In November 2020, the concept of the cloud-based maternal and child service was proposed and promoted by the NHC [16], and the latest technique (cloud computing) was recommended to be applied in MCH services. Data could be stored in either the cloud or the local data center, which improved the energy efficiency ratio of resource usage. Faster cross-institutional and cross-regional business collaboration and data interoperability became available. Three-layer browser/server (B/S) system architecture was adopted in the software based on service-oriented architecture consisting of an application layer, a service layer, and a data layer. Each layer only focused on its own tasks to successfully separate business from logic and client from database, which feasibly met system design requirements. The advantage of the B/S system architecture was obvious because users had the ability to access the system directly using the web browser, providing easy maintenance and high flexibility.

Budget Planning

The construction cost of the RMCIS was based on the provincial or municipal population number, since the population number determines the number of medical institutions and the workload of the system going live and docking. In addition, different function modules led to discrepant prices. The cost for medium-to-large cities with a population of more than 5 million was about CNY 4-6 million (US $555,609-$833,414), while that for small cities with a population of less than 5 million was about CNY 3-4 million (US $416,707-$555,609). This cost included system development, implementation, etc. The maintenance cost is 10% of the total cost per year.

Sustainability

To ensure the sustainability of the RMCIS, several actions were taken. Operation and maintenance management systems were established for all aspects, from funds to personnel. Data collection channels and data management regulations require fixed personnel and procedures to ensure stable and safe data sources. The data backup management system implements regular data backup and ensures that the system can be immediately accessed and restored after failure. The maintenance system monitors operation behavior to ensure correct operation status and avoid attacks, and system emergency plans can maintain business continuity in the case of an emergency. The maintenance fund guarantee system ensures that a certain amount of maintenance investment is kept to promote system updating and upgrading.

An operations and maintenance team was formed and provided by the technology company to ensure operation of the system without disruption. System operation and maintenance mainly include business operation consultancy, data maintenance, software maintenance, and hardware platform maintenance. Remote scheduled manual checking at regular intervals is the basic safeguard. If any system failure occurs, a text message and an email are directly sent to the duty personnel for notification. The time limit for a response to failure is 1 hour, and the repair time limit is 1 hour for major failures and 4 hours for general failures. Technical support is even offered to arrive on-site within a time limit to solve any problem.

As the lead department of the regional MCH system, the regional health care commission took the responsibility for user training. Centralized training and counseling for users was organized after system implementation. In addition, documents and videos of operation tutorial, as well as online support, were provided for users in need.

Data FLow

The RMCIS implemented in Inner Mongolia provides 2 modes of data collection, depending on the management requirements of local health commissions: direct upload mode and front-end processor collection mode. In the direct upload mode, medical institutions directly upload data through the web service interface after strict encryption. In the front-end processor collection mode, the business system of each medical institution first pushes data to the local front-end server, and then the collection client module automatically collects the data and submits them to the provincial maternal and child data center. The RMCIS supports the front-end processor collection mode with automatic data collection and submission. This way, connecting with the HIS, the LIS, the imaging system, financial systems, and other systems, the RMCIS deployed in individual medical institutions is able to collect data from health record information, tests, images, and reports of related MCH services. In addition, the RMCIS obtains information from personalized mobile apps and official WeChat accounts.

Following guidelines of the NHC [32,36], the data collection process of the RMCIS strictly follows standardized criteria to avoid ambiguous information exchange, including data elements, basic data sets, and data dictionaries. In real MCH business activity, relevant information and data are recorded in the form of record forms (eg, birth certificate, newborn disease screening record form, basic maternity registration form), making up 1 or more basic data sets (eg, birth certificate data set, newborn disease screening data set, maternal health services and high-risk management data set). The collection of standardized smallest units of health record data in unified formats, that is, data elements (eg, name, gender code, date of birth, detailed address), constitutes a data set as well as a record form. Taking the record form of birth certificates as an example, the corresponding data set is the birth certificate data set, which consists of the data elements newborn name, newborn gender code, newborn birth date and time, birthplace, etc.

To ensure the quality of collected data, the system automatically monitors and calibrates the uploaded data based on the data quality monitoring rules: accuracy, completeness, consistency, repeatability, and timeliness. In the face of various construction levels of HISs and the quality of data across the province, the provincial MCH data center needs to formulate a unified data set, data dictionary, business forms, quality control rules, etc.

All data are classified by category and regional distribution and displayed vertically from top to bottom, which means higher authorities are able to access the data of the corresponding affiliates. The RMCIS defines permissions for each user of each organization according to their role and authorizes management to access, download, and view statistical reports. In addition, case access and collaborative sharing functions are also provided, that is, as long as the resident's health card is inserted when they visit a health care institution within the province, the health care workers are able to access the resident's MCH information and records online with prior consent.

For data display and visualization, a surveillance module was developed to display relevant indicators, statistical reports, and graphs. Specific reports and graphs form the *Inner Mongolia Annual Report on Maternal and Child Health* [37] based on reporting specifications, including the annual report on maternal health care and health status, the annual report on the health care and health status of children under 7 years, the annual report on the health status of nonfamily children and pregnant women, the annual report on premarital health care, the annual report on the health care work of nurseries and kindergartens, the annual report on the work of midwifery service organizations, the annual report on the monitoring of deaths of children under 5 years, and the quarterly report on the number of perinatal babies. The RMCIS also provides the functions of single or multiple conditional combination queries, as well as printing and exporting query results. These MCH data visualization functions can help with health management decision-making and assist policy makers in determining future regulation outlines for further promotion.

Ethical Considerations

The First Affiliated Hospital of Xiamen University Ethics Committee approved this study (approval number SL-2021KY044-01). All the users consented to sharing the information for using the developed RMCIS. Privacy protection and data security were emphasized with technical support from technicians even before the system was implemented. Specific security solutions were determined by Technical Program for Construction of Regional Maternal and Child Health Information System.

A 3D information security protection system was built to ensure confidentiality, integrity, availability, and controllability spanning the hardware, software, network, system, data, application, and management. The security protection level was set to level 3 because any potential vulnerabilities might influence the social order and public confidence. Since the RMCIS was deployed on the government affairs' cloud, which met the requirements of information security level 3, the physical environment security, computing environment security, security boundary protection, communication network protection, and security management center required for the system all met the requirements.

To ensure data security, security access functions, including permission management, identity authentication, and access control management, were applied. Permission management allows the RMCIS to be controlled no matter what operations a specific user had undertaken, including editing, adding, and deleting. Identity authentication is also one of the main prevention and protection strategies to prevent the core information system from illegal access. Furthermore, access control management guarantee that permissions in the system are determined by user roles. Only specific users, such as government staff, are allowed to access functions with higher permission levels, while the rest of the users can only access modules of their own sections. For safety requirements, the system provides log management, recording modification and log queries. In terms of network security, the system supports links, such as private networks or virtual private networks, to ensure secure data transmission. Encryption and decryption technology, identity authentication, and security policy were used to guarantee the security of data transmission. Lastly, data set disaster recovery, customer data platform disaster recovery, data backup, and graded multiclass disaster recovery were designed and implemented in this study.

Data Collection and Statistical Analysis

This study collected summary data of the RMCIS implementation in 12 cities of Inner Mongolia. Since the system was implemented in Inner Mongolia since January 1, 2020, the speed of informatization construction of the 12 cities varied, so earlier data were not completely uploaded into the system. Partial data from Wuhai, Ordos, and Alaxa were absent because of inaccessibility. The experimental data used in this study only included those collected from Wuhai, Hohhot, and Tongliao in 2020, with partial 2021 data of Wuhai and Alaxa missing. Until October 31, 2022, all 12 cities in Inner Mongolia completed data interoperability with the RMCIS. Thus, the limitations of the data included data missing for extended services in some cities with a short duration.

The study followed the descriptive implementation methodology designed to demonstrate the construction process and implementation effects with the sample size of functional modules and the usage count of services. For distribution of specific users, the basic characteristics of pregnant women (ie, maternal age, gestational week at registration, maternal height, maternal weight, pre-pregnancy BMI, gestational week at delivery, gravidity, education level, parity, current smoking, current alcohol consumption, mode of delivery, multiple gestations) and that of newborns (ie, birth length and birth weight) were collected. Five-color management results were presented in a pie chart for ratios and a histogram for the top 10 factors as an example of high-risk management. The usage count per year for services (ie, pregnancy registry, delivery, newborn, premarital checkup, and CC and BC screening) and pregnancies (ie, total pregnancies and high-risk pregnancies) was displayed to demonstrate its application effects in each city. All these data were securely stored by Zoe Software Engineering Co, Ltd (Xiamen City), which cooperates with medical institutions to run the RMCIS. The company deidentified these data and constructed an internet environment for secure analysis, obtaining data according to the principle of minimum availability. After analyzing the data in the intranet security environment, the analysts exported the analytical results rather than the underlying data.

Project summary data, including duration, labor cost, and cost for each period, were provided by the project team of Zoe Software Engineering Co, Ltd. Other basic information, such as the MMR, NMR, and UMR, were shown on the website of the People's Government of Inner Mongolia Autonomous Region.

Descriptive analysis was performed using Microsoft Excel 2016. In addition, the aggregation and analysis of the top 10 factors of five-color management were performed using Python 3.10.7.

Results

Cost Summary

Project planning was initiated at the end of 2018, and the RMCIS was implemented in January 2020, with a duration of 13 months. The labor cost was 210 person-months, and the cost was CNY 8 million (US $1.1 million). In the 4-year maintenance, the first year was free and the later 3 years cost CNY 800,000 (US $111,142; 10% of the implementation cost) per year, leading to a total cost of CNY 10.4 million (US $1.4 million). See Table 3 for details.

Table 3. Duration, labor cost, and system construction cost.

Project period	Duration (months)	Labor cost (person-months)	Cost (million CNY)
Planning	2	10	0.5 (US $69,463)
Design, and research and development	8	140	5.5 (US $764,111)
Deployment	3	60	2.0 (US $277,858)
Total	13	210	8.0 (US $1.1 million)

Data Characteristics

In Inner Mongolia, the RMCIS covered 278 hospitals and 225 community health care centers in 12 cities. The main modules launched included pregnancy care, childbirth care, and maternal care. A total of 221,772 pregnancy registries, with a 44.75% (n=99,241) early pregnancy registry rate, were recorded in the system, along with 1,417,066 records of antenatal visits and 145,863 pregnancies for intrapartum care and delivery care. In addition, records of 147,264 newborns were maintained in the childbirth care module, with medical information including weight, height, newborn disease screening, etc. From January 1, 2020, to October 31, 2022, 56,430 people underwent premarital checkups and 256,659 women underwent CC and BC screening (Table 4).

Table 4. Usage count of main modules and services in the RMCIS[a] (January 1, 2020-October 31, 2022).

Module and services[b]	Data	Value
Pregnancy care		
Pregnancy registry	Pregnancies, N	221,772
Pregnancy registry	Early pregnancies, n/N (%)	99,241/221,772 (44.75)
Antenatal visit	Records, N	1,417,066
Antenatal visit	Pregnancies, n/N (%)	202,879/1,417,066 (14.32)
Intrapartum care	Pregnancies, n/N (%)	147,510/202,879 (72.71)
Intrapartum care	Deliveries, n/N (%)	145,863/147,510 (98.88)
Intrapartum care	High-risk pregnancies, n/N (%)	83,376/147,510 (56.52)
Childbirth care	Newborns, N	147,264
Maternal care		
Premarital health care	People, N	56,430
CC and BC[c] screening	Women, N	256,659

[a] RMCIS: regional maternal and child information system.

[b] For each service, the duration was from January 1, 2020 to October 31, 2022.

[c] CC and BC: cervical cancer and breast cancer.

The pregnancy registry, antenatal visits, and intrapartum care services had been put to use, while antenatal screening, postnatal follow-up, and kindergarten checkup data were still deficient. Note that the data of CC and BC screening were maintained in the RMCIS only from January 2022, because this service was applied using other systems previously.

The median maternal age was 30 (lower quartile [Q_L]-upper quartile [Q_U] 27-33) years, the median gestational week at pregnancy registration was 14 (11-22) weeks, and the median gestational week at delivery was 39 (38-40) weeks. The median birth length and birth weight of newborns were 50 (50-51) cm and 3300 (Q_L-Q_U 2990-3600) g (Table 5). Gravidity refers to the number of pregnancies, including current and past ones. A total of 20,165 (19.52%) pregnancies were multiparous, which meant a woman had more than 1 delivery of a fetus at or after the 24th gestational week, while the rest of the pregnancies (n=83,134, 80.48%) were nulliparous (no birth history). Only 926 (0.44%) pregnant women had a habit of smoking, and 724 (0.35%) currently consumed alcohol. A total of 48,135 (43.35%) deliveries were conducted by caesarean section, although WHO set a warning cutoff for the rate of cesarean section as less than 15% [38]. See Table 6 for the details.

Table 5. Numerical characteristics of pregnant women and newborns recorded in the RMCIS[a] (January 1, 2020-October 31, 2022).

Numerical characteristic	Median (Q_L-Q_U)[b]	Total pregnant women/newborns, n	Missing values, n (%)
Maternal age (years)	30 (27-33)	246,167	0[c]
Gestational weeks at registration	14 (11-22)	244,743	1424 (0.58)[c]
Maternal height (cm)	162 (158-165)	246,146	21 (0.01)[c]
Maternal weight (kg)	62 (55-70)	242,128	4039 (1.64)[c]
Pre-pregnancy BMI (kg/m^2)	23.83 (21.33-26.84)	242,128	4.39 (1.64)[c]
Gestational weeks at delivery	39 (38-40)	147,510	0[d]
Gravidity (times)	1 (1-3)	147,510	0[d]
Birth length (cm)	50 (50-51)	147,171	0[e]
Birth weight (g)	3300 (2990-3600)	147,171	0[e]

[a] RMCIS: regional maternal and child information system.

[b] Q_L: lower quartile; Q_U: upper quartile.

[c] N=246,167 (number of pregnancies in antenatal care).

[d] N=147,510 (number of pregnancies in delivery care).

[e] N=147,171 (number of newborns in childbirth care).

Table 6. Categorical characteristics of pregnant women recorded in the RMCIS[a] (January 1, 2020–October 31, 2022).

Categorical characteristics	Pregnant woman, n (%)	Missing values, n (%)
Education level	120,665 (100.00)	125,502 (50.98)[b]
No education or semiliterate	352 (0.29)	—[c]
Primary education	4777 (3.96)	—

[a] RMCIS: regional maternal and child information system.

[b] N=246,167 (number of pregnancies in antenatal care).

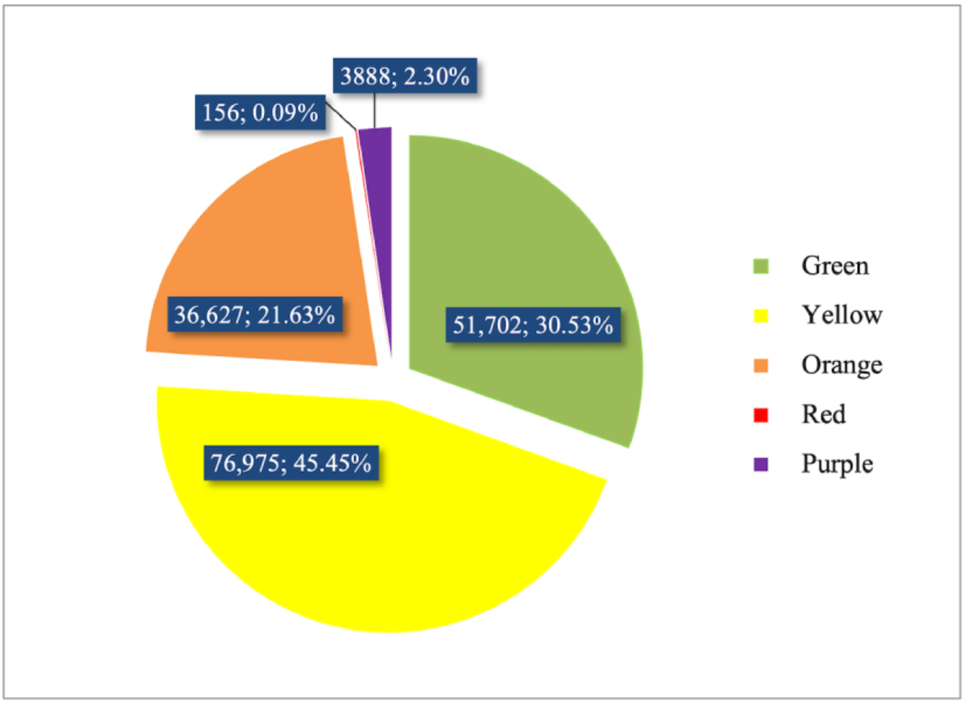
[c] Not applicable.

[d] N=147,510 (number of pregnancies in delivery care).

Pregnancy Risks and Factors

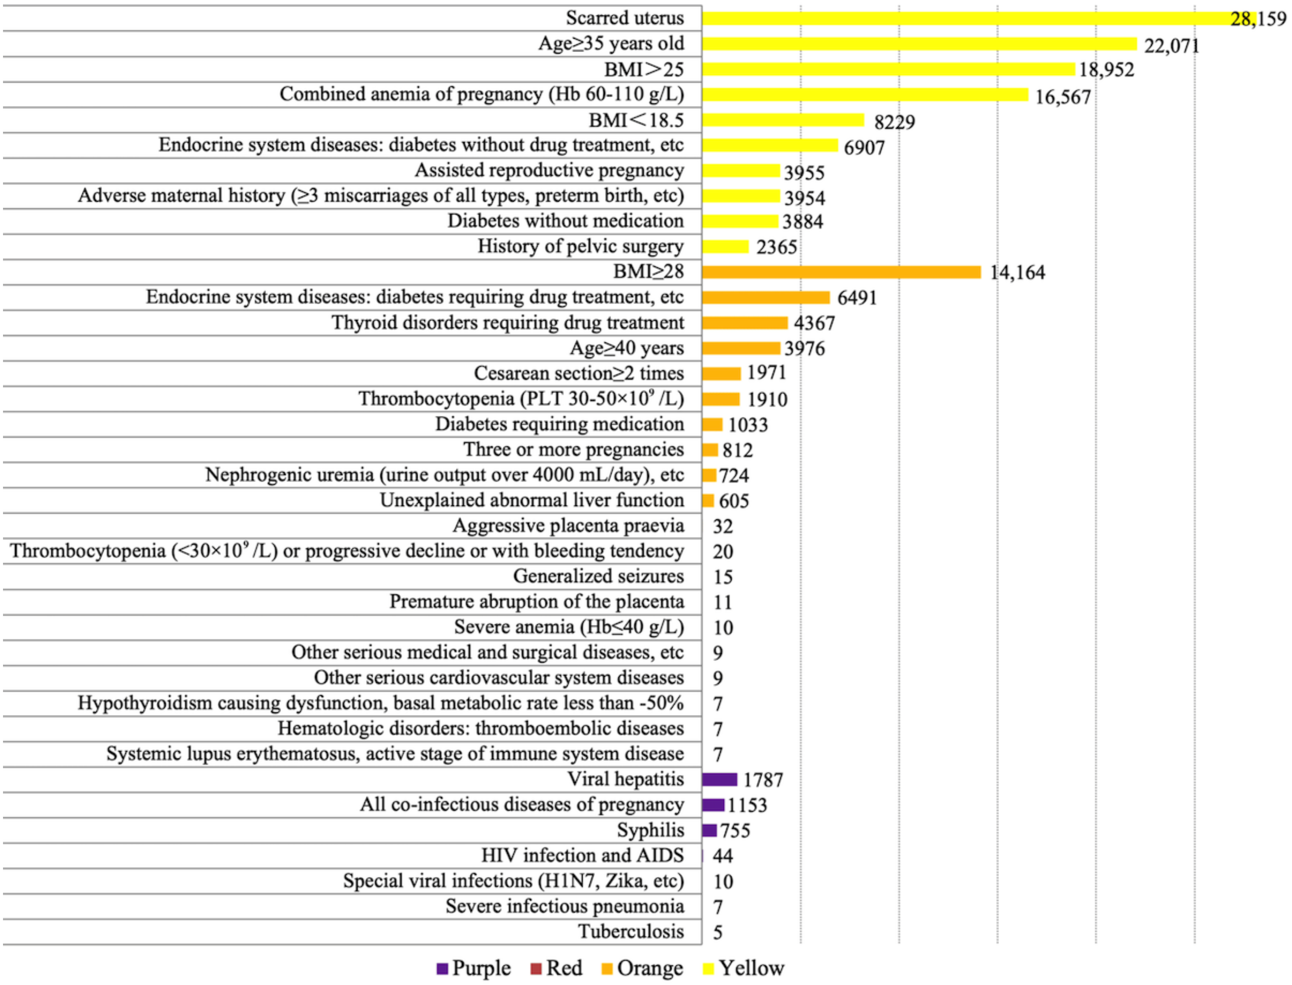
The RMCIS provided statistics for 5-color management. In total, 51,702 (30.53%) pregnancies were marked green (no pregnancy complications). Pregnancies marked yellow (general risk) accounted for the largest proportion (n=76,975, 45.45%), and 36,627 (21.63%) pregnancies were marked orange (relatively high risk). Only 156 (0.09%) pregnant women were marked red (high risk). Furthermore, pregnancies marked purple (infectious disease) were 3888 (2.30%) in total (Figure 4).

Figure 4. Numbers and percentages in 5-color pregnancy risk management (January 1, 2020–October 31, 2022).



For yellow risk, the top 4 factors accounting for 74.54% of cases were scarred uterus (n=28,159, 36.58%), age≥35 years (n=22,071, 28.67%), BMI>25 (n=18,952, 24.62%), and combined anemia of pregnancy (hemoglobin 60-110 g/L; n=16,567, 21.52%). For orange risk, BMI≥28 (n=14,164, 38.67%) accounted for almost 40% of cases and the 3 reasons were endocrine system disease (eg, diabetes requiring drug treatment, thyroid disease, pituitary prolactinoma, etc; n=6491, 17.72%), thyroid disorders requiring drug treatment (n=4367, 11.92%), and age≥40 years (n=3976, 10.86%). Red risk only accounted for 156 (0.09%) cases, and aggressive placenta praevia (n=32, 20.51%) was the most influencing factor. For purple risk (infectious disease), viral hepatitis (n=1787, 45.96%), all coinfectious diseases of pregnancy (n=1153, 29.66%), and syphilis (n=755, 19.42%) were the top 3 factors, accounting for over 98% of cases (Figure 5).

Figure 5. Top 10 factors and number of high-risk pregnancies (yellow, orange, red, purple) from January 1, 2020, to October 31, 2022..



Implementation and Popularity

Major modules and services were put into use in 2020, while the minor ones were not due to system transformation and various other reasons.

The 3 main modules put into use were pregnancy care, childbirth care, and maternal care. For pregnancy registry and delivery, the number of pregnant women doubled from 2020 to 2022. The number of newborns increased by almost 1000 every year. Premarital checkup data started to be recorded from 2021, and CC and BC screening was recorded from 2022, since previous data were maintained using other systems alternatively (Table 7).

In 2020, only 3 cities chose to apply and upload MCH data to the RMCIS, while in 2021, Wuhai and Alxa still used their own municipal MCH systems, and parts of cities only uploaded partial data to the system. Yet, now, all 12 cities have participated and contributed to the RMCIS construction in Inner Mongolia. Until October 2022, 132,079 pregnancies were registered in the system, with 65,018 (49.23%) high-risk pregnancies, compared to only 32,466 pregnancy registrations in 2020. The number of pregnancies managed in the system increased by 157.9% in 2021 and 57.74% in 2022 (until October). The popularity of RMCIS implementation is high, and the result of the whole regional MCH data interconnection is significant (Table 8).

Table 7. Annual usage count of major services (January 1, 2020-October 31, 2022).

Year	Pregnancy registries, n (%)	Deliveries, n (%)	Newborns, n (%)	Premarital checkup, n (%)	CC and BC[a] screening, n (%)
2020	45,374 (46.25)	30,211 (30.79)	22,520 (22.95)	0	0
2021	87,245 (47.20)	46,942 (25.40)	23,609 (12.77)	27,044 (14.63)	0
2022[b]	91,106 (19.36)	68,358 (14.52)	25,231 (5.36)	29,350 (6.24)	256,659 (54.53)

[a] CC and BC: cervical cancer and breast cancer.

[b] Until October 31, 2022.

Table 8. Annual and high-risk pregnancies in 12 cities of Inner Mongolia (January 1, 2020–October 31, 2022).

City	2020		2021		2022a	
	Pregnancies (n=32,466), n (%)	High-risk pregnancies (n=21,849, 67.30%), n (%)	Pregnancies (n=83,734), n (%)	High-risk pregnancies (n=39,466, 47.13%), n (%)	Pregnancies (n=132,079), n (%)	High-risk pregnancies (n=65,018, 49.23%), n (%)
Ordos	0	0	116 (0.19)	31 (0.08)	43,962 (33.28)	19,756 (30.39)

Alxa	0	0	0	0	705 (0.53)	330 (0.51)

Discussion

Principal Findings

This study described the construction process (system architecture, functional modules, and construction costs) of the RMCIS in Inner Mongolia and demonstrated the implementation effects with popularity (the usage of main services and 5-color management of pregnancy risks) and challenges. Based on the data collected, the RMCIS implementation was found to have many social and economic benefits, providing a feasible solution to RMCIS construction.

Social Benefits

The first social benefit was the achievement of MCH medical resource integration, providing supervision tools for governments, data sharing for medical institutions, and easy access to medical resources for residents. Basic services of pregnancy care, childbirth care, and maternal care were put into use. The whole MCH process was optimized through data interconnection and fast resource allocation (eg, hospital transfer, delivery bed appointment) [17]. Clinical decision support and intelligent health management helped health care providers make decisions and improve patient care [39]. The RMCIS also provided clear insight for users through calculated indicators, tables, and charts, leading to advanced performance appraisal tools for governments and administration departments. The quality, efficiency, and equity of regional MCH services were improved for the purpose of universal health coverage [40].

Furthermore, the RMCIS was linked to other public health data sets (eg, birth and death certificate data sets). Studies on MCH can be conducted based on the data collected by the system, and a few studies with a specific historical background have become available. Recently, the research priorities in MCH shifted to COVID-19 during the pandemic era worldwide [41]. Regarding domestic policies in China, the effects of the 1-child policy on MCH were also a hot topic [42]. Indicators or MCH outcomes can be compared within different regions of China or with other countries. Otherwise, since the system tries to cover the whole MCH care process for patients, long-term follow-up studies on sequela after delivery (eg, pelvic floor dysfunction after vaginal delivery [43] or uterus rupture after cesarean delivery [44]) or rehabilitation therapy effects on children with birth defects [45] are feasible. Thanks to large-scale data, techniques, such as big data, provide the basic foundation to build models to predict maternal outcomes. Some factors leading to death or birth defects can be explored [46,47]. Moreover, rare cases can be investigated due to the construction of special case databases. As Figure 2 shows, services, such as thalassemia prevention and control, neonatal defect screening, high-risk pregnancy case management, and high-risk children case management, were included in the RMCIS, and thus special case databases were built. After high-risk patients are detected during diagnosis and treatment, they are included in special case management and attract specific attention. Based on special case data, potential scientific studies focusing on rare cases can be conducted. Maternal anemia [48], gestational diabetes with weight gain [49], and high-risk newborn outcomes [50] are hot topics studied by medical workers. In addition, information about birth defects, children with medical handicaps, and growth retardation on stature or brain power is recorded and linked to other systems. Based on this, a new MCH data source profile can be built. For instance, a new data source profile, the Xiamen Registry of Pregnant Women and Offspring (REPRESENT), was developed [51], linking the 4 major health care data platforms: Resident Healthcare Management Platform, Primary Healthcare Management Platform, Electronic Healthcare Records Platform, and Maternal and Child Health Management

Platform. The profile provided further potential uses of pregnancy registry data.

Economic Benefits

The most important economic gain was the reduction in the operating costs for health care institutions and the medical fee for patients [17]. The workflow was further optimized within various institutions at all levels, and staff was streamlined. The problems of inner-hospital duplicate examinations and medications caused by the inability to share information were mitigated, directly reducing the wastage of health resources. Combined with the reform of medical insurance currently promoted in China [52], the medical fee charged became reasonable and acceptable. Finally, the operation efficiency of entire health care services was enhanced so that the sunk costs for institutions and patients decreased.

Challenges and Strategies

First, the biggest barrier to start-up was the huge financial requirement, since an MCIS does not generate direct economic effects but otherwise requires high operation and maintenance costs. The technology company seeks economic benefits, while medical institutions and governments only accept cost-effective ones. This benefit leverage between these parties can potentially hinder the migration of the system. Especially in low-income areas, deficient expenditure can lead to insufficient technical equipment, a lack of training opportunities, a high turnover rate of medical workers, and demotivation of patients. With a relative shortage of medical workers who even have to wear multiple hats, the use of helpful information systems can free them from tedious and repetitive tasks so that they can engage in more rewarding work. Investment at once with a low maintenance cost in exchange for a high degree of informatization helps with rationalization of staffing, MCH service quality improvement for residents, and more straightforward management for governments.

Second, a key factor affecting the RMCIS construction was technology compatibility and data interoperability, similar to the issues in other areas. Making the system compatible with other internal systems and public health databases demands high coordination between institutions and technology companies. On a policy level, strong policy support of governments is indispensable for participating parties to collaborate with clear objectives. On a technical level, standardized criteria of data collection should be predesigned. In fact, the implementation of the system does not indicate full coverage of MCH services. Prior interface standards for core functions are required to ensure the realization of basic services. Other interfaces for extended services (eg, postnatal follow-up, kindergarten checkups) can be further expanded and improved according to the experience in Inner Mongolia.

Third, the demotivation of health care workers was common during the implementation process. Since some medical institutions kept paper records, the application of the RMCIS was considered inferior than that of other basic information systems by staff. In addition, some of the health care workers preferred to provide medical instructions by experience, without intelligent decision-making support. The conversion of treatment habits was challenging. In Inner Mongolia, in addition to helpful tutorials and routine training opportunities, administrative tools, such as performance appraisal, were also used to regulate health care workers' behavior.

Fourth, after operation, requirements of rapid upgradation or optimization for the system were frequently raised to meet new needs, demanding capacity and efficiency from the maintenance team. During the CONVID-19 pandemic, measures, such as epidemiological investigation, real-time reporting of fever clinics, and polymerase chain reaction tests, were required to be added. The technical team was skilled, with ample experience. The RMCIS was used in 2 provinces (Inner Mongolian Autonomous Region and Jiangxi Province), in 6 cities (Xiamen, Fujian; Longyan, Fujian; Pingxiang, Jiangxi; Xinyu, Jiangxi; Jingdezhen, Jiangxi; and Dongying, Shandong) and 7 MCH hospitals. Engineers of the technology company and local technical teams are participating in development and maintenance work. The operation and maintenance management system (as mentioned in the *Sustainability* section) of the RMCIS is referenceable for other areas.

Fifth, network security and privacy security are nonnegligible. The network security law requires information security level protection and level assessment for compliance [53]. It also requires the implementation of sensitive data classification and classification protection. Protecting the data from attacks is a task. Considering the balance of convenience and security, B/S architecture with a private network was deployed in the RMCIS. Each medical institution can use the private network instead of the internet to access the system. This technical solution will provide a higher level of network and privacy security.

Finally, the direct upload mode of data collection (as mentioned in the *Data Flow* section) can lead to some issues. The RMCIS cannot automatically collect and submit data, requiring a data entry team to manually upload MCH records to the system. Every time after a routine production inspection, pregnant women need to take extra efforts to look for a data entry team member to enter her records in the MCHH, which demotivates patients. Since some information can be urgent, the manual uploading process impedes the data flow. Staff even have to call patients for verification if any data are missing. Such inconveniences occurred due to the management requirements of some local health commissions, resulting in duplicate work. Thus, the front-end processor collection mode used in Inner Mongolia is highly recommended for migration.

Due to the homogeneity of the maternal and child service process, the migration of the RMCIS seems feasible. In conclusion, governments should provide strong policy and financial support; medical infomatic constructors need to ensure data interoperability, security, and sustainable maintenance; administration departments in medical institutions should provide routine training opportunities and performance appraisal to motivate doctors; and medical workers are encouraged to keep pace with new techniques. These countermeasures have proven to be effective for the implementation of the RMCIS in Inner Mongolia, which might inspire other areas and even other countries.

Limitations of the Study

The study has several limitations. The period for which data were collected was relatively short, covering less than 3 years. Cities except Wuhai and Hohhot had not used a municipal MCIS before the implementation of the RMCIS, leading to missing data in 2020 and 2021. Extended services (eg, antenatal screening, postnatal follow-up, and kindergarten checkups) are still unused in the system, as further data interoperability with interfaces is awaited. Due to concerns of data security, the data collected in this study were deidentified and privacy-related data, including infectious diseases, were omitted. The artificial techniques used in the RMCIS are still immature, and the accuracy of clinical decision remains to be verified. Further studies can include benefits and outcomes, such as the impact on MCH outcomes, efficiency of health care delivery, patients' system management rate, and patient satisfaction, to evaluate the implementation effects of the RMCIS.

Conclusion

Based on the field study in Inner Mongolia, regional MCH improved through the effective implementation of an RMCIS. The system showed significant social and economic benefits, providing supervision tools for governments, provincial MCH data sharing for medical institutions, clinical decision support for health care workers, real-world data for researchers, and easy access to medical resources for residents. We can foresee that this large-scale application of an MCIS can further improve the quality, efficiency, and equity of MCH services in Inner Mongolia and provide valuable experience to medical administration departments, practitioners, and medical informatic constructors worldwide.

Acknowledgments

This study was funded by the 2021 Xiamen Medical and Health Guidance Project "Research on Theoretical and Empirical Evaluation of Internet Hospital Services" (3502Z20214ZD1003); the Xiamen Municipal Health Commission, Xiamen Municipal Bureau of Science and Technology (3502Z20209005); the Fujian Provincial Clinical Research Center for Brain Diseases (2021FJSLCYX01); and the Xiamen Clinical Research Center for Neurological Diseases (2021XMSLCYX0). We are grateful to all the participators who contributed to this study.

Data Availability

The data sets including patients' individual information are not publicly available due to privacy protection and data security regulations. With the consent of the local health commission, the technology company in charge of system development and maintenance generated summary data according to the analysis requirements for this study, which have all been included in this paper.

Authors' Contributions

ZW and KG contributed to the study concept and design. JC and XL contributed to data acquisition. YZ and YL contributed to manuscript preparation and figure/table drawing. YY and CX performed data analysis and drafted the manuscript. All authors have contributed to the interpretation of the results and have approved the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The use of a smartphone built-in microphone for auscultation is a feasible alternative to the use of a stethoscope, when applied by physicians.

Objective: This cross-sectional study aims to assess the feasibility of this technology when used by parents—the real intended end users.

Methods: Physicians recruited 46 children (male: n=33, 72%; age: mean 11.3, SD 3.1 y; children with asthma: n=24, 52%) during medical visits in a pediatric department of a tertiary hospital. Smartphone auscultation using an app was performed at 4 locations (trachea, right anterior chest, and right and left lung bases), first by a physician (recordings: n=297) and later by a parent (recordings: n=344). All recordings (N=641) were classified by 3 annotators for quality and the presence of adventitious sounds. Parents completed a questionnaire to provide feedback on the app, using a Likert scale ranging from 1 (“totally disagree”) to 5 (“totally agree”).

Results: Most recordings had quality (physicians’ recordings: 253/297, 85.2%; parents’ recordings: 266/346, 76.9%). The proportions of physicians' recordings (34/253, 13.4%) and parents' recordings (31/266, 11.7%) with adventitious sounds were similar. Parents found the app easy to use (questionnaire: median 5, IQR 5-5) and were willing to use it (questionnaire: median 5, IQR 5-5).

Conclusions: Our results show that smartphone auscultation is feasible when performed by parents in the clinical context, but further investigation is needed to test its feasibility in real life.

Introduction

Respiratory diseases are leading causes of morbidity and mortality worldwide, and infants and young children are particularly vulnerable. Asthma is the most common chronic respiratory disease in children, affecting approximately 14% of children globally, and its prevalence is increasing [1,2]. Health care costs associated with respiratory diseases are increasing burdens on the global economy, including primary and inpatient health care costs; disability-adjusted life-years; and lost productivity, with a high number of school and work days lost [3,4].

Remote monitoring strategies can play an important role in controlling symptoms, improving patients' quality of life, and detecting adverse events that are associated with significant morbidity [5,6]. Lung auscultation is a quick, inexpensive, and efficient way to assess the respiratory system and help monitor a child's respiratory status [7,8]. However, as auscultation with a stethoscope is commonly performed by a physician during in-person visits, there is a need for suitable alternatives that support teleconsultation and empower families to take control of their own health and others' health.

As the ownership of a smartphone is now extremely common, Reyes et al [8] and Ferreira-Cardoso et al [9] recently proposed using a smartphone to acquire lung sounds; the former used an electret microphone connected to a smartphone, and the latter used smartphone built-in microphones. Ferreira-Cardoso et al [9] showed that smartphone auscultation performed by a physician was feasible in children. However, it remains unknown whether smartphone auscultation would be feasible if performed by parents and whether they would accept the use of this technology outside the clinical setting [9,10].

The primary aim of our study was to compare the feasibility of smartphone auscultation when performed by parents versus physicians. As a secondary aim, we evaluated the acceptability and ease of use of this technology among parents.

Methods

Ethical Considerations

This study was approved by the ethics committee of Centro Hospitalar Universitário de São João (approval number: 316/20; September 18, 2020). This study was reported in accordance with the recommendations of the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) Initiative [11]. Written informed consent was obtained from the parents, and assent was obtained from the children. In accordance with national legislation, written informed consent was also obtained from the children if they were aged 16 years or older.

Study Design

We conducted a cross-sectional study with a convenience sample of children who were followed at the pediatrics department of the Centro Hospitalar Universitário de São João, a tertiary care public hospital in Porto, Portugal. This study took place between December 2022 and May 2023. During medical visits, the physicians invited the children and their parents to participate in this study.

Participants

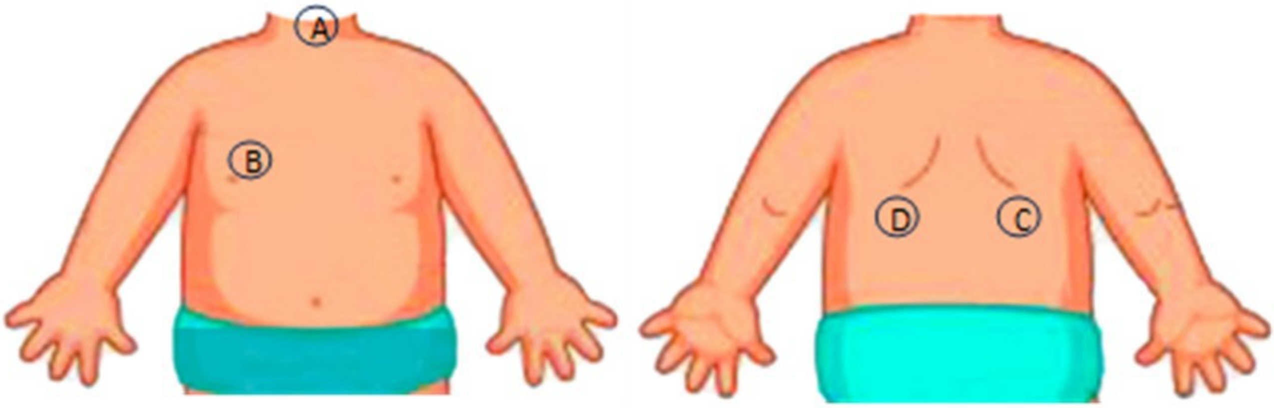
Children aged 5 to 17 years, with or without a respiratory disease (eg, asthma, cystic fibrosis, and other respiratory diseases), were included if they had a scheduled medical visit. The exclusion criteria were refusal to participate in this study and any health status or condition that interfered with the correct and safe collection of the children's lung sounds.

Data Collection

Data on children's sex, age, height, weight, and diagnosis were registered in a paper case report form. BMIs were calculated from the anthropometric data.

Smartphone lung auscultation was performed by the physicians, using the AIRDOC mobile app [10]. The app has multiple features, but only the lung auscultation feature was used for this study. A full description of the app can be found elsewhere [9,10]. During auscultation, the child was seated in an upright position. Auscultation was performed at the following four locations: the three minimum locations recommended for computerized respiratory sound analysis [12]—the trachea and the right and left posterior lung bases—and the right anterior chest, which is known to give a better sense of the presence of adventitious sounds in children (Figure 1) [13,14].

Figure 1. Lung auscultation locations: (A) trachea, (B) right anterior chest, (C) right posterior base, and (D) left posterior base.



Two 10-second recordings were made at each location, allowing for the inclusion of 1 to 5 respiratory cycles per recording [15]; 2 physicians (ie, 1 physician and 1 final-year medical student) were responsible for making the recordings, using their respective smartphones—an Apple iPhone XR (Apple Inc) and an Apple iPhone 14 (Apple Inc).

After the physicians completed the smartphone auscultations, the parents were invited to participate and were briefly instructed to perform the auscultation by using the same procedures and the same smartphones used by the physicians. Afterward, the parents completed a 3-item questionnaire to provide feedback on the app (app's ease of use for recording lung sounds, willingness to use the app to send lung sounds to the physician, and recommendation to others), using a Likert scale ranging from 1 ("totally disagree") to 5 ("totally agree").

Lung Sound Recording Classification

Each lung sound recording was listened to independently by 3 annotators—a physiotherapist and lung sound expert (CJ), a medical doctor (HFC), and a final-year medical student (CSS)—using Adobe Audition 2023 version 23.2 (Adobe Inc) and high-quality headphones (Marshall Major IV [Zound Industries], SONY Wh-H910Nl [Sony Group Corporation], and Sennheiser HD 380 Pro [Sennheiser electronic GmbH & Co. KG]). They also performed an analysis of sound spectrograms according to the default parameters of Adobe Audition. The three annotators were blinded to all data collected except child IDs and auscultation locations. Despite the shorter duration (10 s instead of the recommended 15 s), the quality of each lung sound recording was assessed according to the European Respiratory Society's criteria for sounds with quality (ie, minimal artifacts, visible respiratory phases, and a sound of interest could be demonstrated) [16]. The final decision on the quality of recordings was made by consensus among the three annotators. The next step was to evaluate only the lung sound recordings with quality in terms of the presence of adventitious sounds, namely, crackles and wheezes [17]. The final decision as to whether adventitious sounds were present was made by majority rule.

Data Analysis

Descriptive statistics were used to characterize the participants (ie, sex, age, weight, height, BMI, and diagnosis group [asthma, other respiratory disease, and no respiratory disease]). Shapiro-Wilk tests were used to assess the normality of the data. To explore the existence of differences among the three diagnostic groups, a chi-square test (sex), Kruskal-Wallis test (weight and BMI), and 1-way ANOVA (age and height) were applied.

The proportions of agreement and the proportions of specific agreement (specific agreement for each category) among the three annotators were calculated. Afterward, their interrater reliability was determined by using the Fleiss κ and its 95% CI. The Fleiss κ was interpreted as follows: 0 to 0.20 indicated slight agreement, 0.21 to 0.40 indicated fair agreement, 0.41 to 0.60 indicated moderate agreement, 0.61 to 0.80 indicated substantial agreement, and 0.81 to 1.0 indicated almost perfect agreement [18]. This was done for each auscultation group (ie, physicians and parents) and for each location. Differences in agreement among locations were explored with chi-square tests, and Bonferroni correction was used where necessary.

The proportions of quality recordings and recordings with adventitious sounds were calculated for each auscultation location and auscultation group. Chi-square tests, in which Bonferroni correction was used when necessary, were applied to assess differences among locations. All main analyses were based on the recordings, which were the de facto subjects of analysis in this paper. However, a secondary, more clinically oriented analysis was carried out in parallel by calculating the proportions of participants with at least 1 lung sound recording with quality and at least 1 lung sound recording with adventitious sounds. This was also done for each location and each auscultation group.

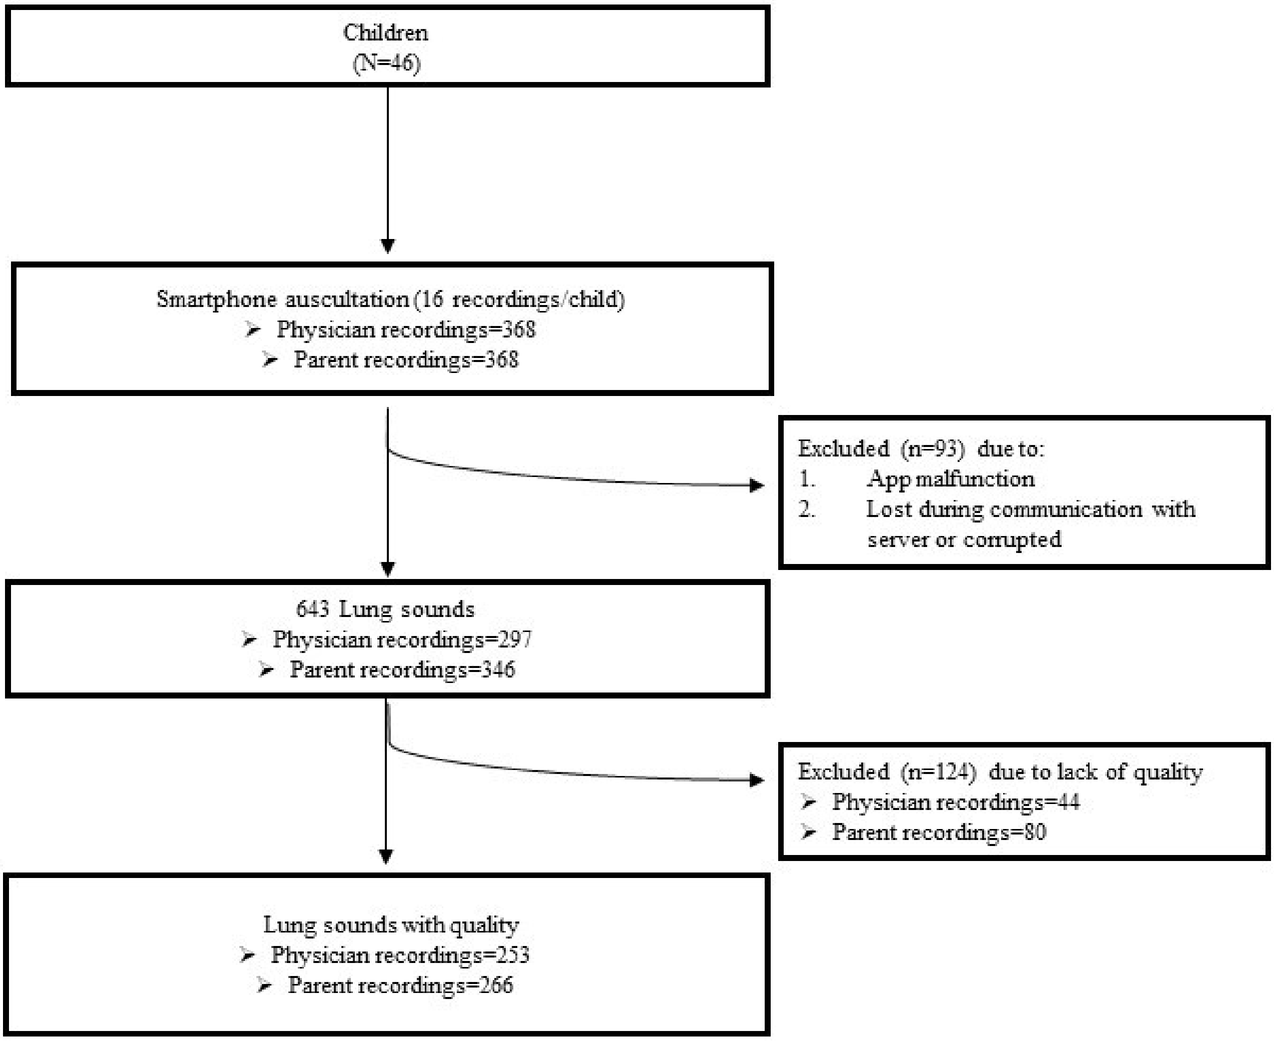
The statistics software used was IBM SPSS Statistics (version 28.0.0.0; IBM Corp). R software was used to compute the proportions of agreement with the "obs. Agree" package (R Foundation for Statistical Computing). The level of significance was set at .05.

Results

Participants' Characteristics

A total of 46 children were recruited. Most were male (n=33, 72%) and had asthma (n=24, 52%). The mean age was 11.3 (SD 3.1) years. The median BMI was 19.4 (IQR 16.4-21.5) kg/m^2. The characteristics of the participants are presented in Multimedia Appendix 1. A total of 736 recordings were expected from the 46 children (16 recordings/child), but due to some data losses, 641 (87.1%) recordings from 45 children were analyzed (Figure 2). All 45 children had recordings from both physicians and parents for each location except the right anterior chest, which was missed by the physician for one child and by the parent for another.

Figure 2. Flowchart showing the number of lung sound recordings and children considered throughout this study.



Lung Sound Quality: Agreement and Proportion

The proportion of agreement among the three annotators regarding the quality of the physicians' lung sound recordings (91%) was similar to that for the quality of parents' lung sound recordings (85%), corresponding to a Fleiss κ of 0.66 (95% CI 0.59-0.72) and 0.57 (95% CI 0.51-0.63), respectively (Table 1). With regard to the physicians' recordings, agreement for recordings taken at the trachea was greater than that for recordings taken at the right anterior and posterior locations (Multimedia Appendix 2). No statistically significant differences in the agreement among locations were found in the parents' recordings (Multimedia Appendix 2).

Table . Interrater reliability and proportions of agreement (PAs) among experts on the lung sound quality of physicians' and parents' lung sound recordings.

Location and quality of recordings		Physicians' recordings		Parents' recordings	
		Fleiss κ (95% CI)	PA (95% CI)	Fleiss κ (95% CI)	PA (95% CI)
Trachea		0.50 (0.37-0.63)	0.99 (0.97-1.00)	0.51 (0.39-0.63)	0.90 (0.84-0.95)
	No quality	N/A[a]	0.50 (0.50-0.50)	N/A	0.57 (0.37-0.73)

All locations		0.66 (0.59-0.72)	0.91 (0.89-0.94)	0.57 (0.51-0.63)	0.85 (0.82-0.88)
	No quality	N/A	0.71 (0.62-0.78)	N/A	0.66 (0.59-0.72)
	Quality	N/A	0.95 (0.93-0.97)	N/A	0.90 (0.88-0.92)

[a] N/A: not applicable.

The proportion of quality recordings was high—85.2% (253/297) for recordings obtained by physicians and 76.9% (266/346) for recordings obtained by parents (Table 2). The proportion of quality recordings at the trachea was statistically superior to all other locations for the physicians' recordings and superior to the right posterior base for the parents' recordings (Multimedia Appendix 2). When using the participants (n=45) as the unit of analysis, the majority had at least 1 lung sound recording with quality per location when recordings were acquired by the physicians (n=30, 67%) and when they were acquired by parents (n=27, 60%).

Table . Proportions of physicians' lung sound recordings and parents' lung sound recordings with quality.

Location of recordings	Quality lung sound recordings, n/N (%)	
	Physicians' recordings	Parents' recordings
Trachea	75/76 (98.7)	64/74 (86.5)
Right anterior chest	57/76 (75)	53/75 (70.7)
Right posterior base	63/73 (86.3)	48/70 (68.6)
Left posterior base	58/72 (80.6)	59/70 (84.3)
All locations	253/297 (85.2)	266/346 (76.9)

Adventitious Sounds: Agreement and Proportion

The proportion of agreement among the three annotators regarding the presence of adventitious sounds was 91% (κ=0.60, 95% CI 0.53-0.68) for recordings obtained by physicians and 91% (κ=0.62, 95% CI 0.55-0.70) for those obtained by parents (Table 3). No statistically significant differences in the agreement were seen when considering locations separately (all *P* values were >.05).

Table . Interrater reliability and proportions of agreement (PAs) among experts on the presence of adventitious sounds in the physicians' and parents' lung sound recordings.

Recording location and presence of adventitious sounds		Physicians' recordings		Parents' recordings	
		Fleiss κ (95% CI)	PA (95% CI)	Fleiss κ (95% CI)	PA (95% CI)
Trachea		0.63 (0.49-0.76)	0.91 (0.86-0.95)	0.45 (0.31-0.59)	0.86 (0.78-0.92)

	Present	N/A	0.65 (0.54-0.75)	N/A	0.67 (0.55-0.77)

[a] N/A: not applicable.

Adventitious sounds were found in 13.4% (34/253) and 11.7% (31/266) of the recordings obtained by physicians and parents, respectively (Table 4). Comparisons between auscultation locations showed no significant statistical differences (all *P* values were >.05).

Table . Proportions of physicians' lung sound recordings and parents' lung sound recordings with adventitious sounds.

Location of recordings	Recordings with adventitious sounds, n/N (%)	
	Physicians' recordings	Parents' recordings
Trachea	12/75 (16)	8/64 (12.5)
Right anterior chest	7/57 (12.3)	9/53 (17)
Right posterior base	10/63 (15.9)	4/48 (8.3)
Left posterior base	5/58 (8.6)	3/59 (5.1)
All locations	34/253 (13.4)	31/266 (11.7)

When using the participants (n=45) as the unit of analysis, 19 (42%) participants had at least 1 lung sound recording with adventitious sounds (19 such recordings were obtained by the physician, and 17 such recordings were obtained by the parents).

Parents' App Feedback

As can be seen in Table 5, overall, the parents would recommend the app to others (questionnaire: median 5, IQR 5-5), found it easy to work with (questionnaire: median 5, IQR 5-5), and were willing to use it to send lung sounds to the physician (questionnaire: median 5, IQR 5-5).

Table . Parents' (n=45; 1 missing response) feedback about the app.

Questionnaire item	App feedback, n (%)				
	Totally agree	Agree	Neither agree nor disagree	Disagree	Totally disagree
App's ease of use for recording lung sounds	39 (87)	4 (9)	0 (0)	1 (2)	1 (2)
Willing to use the app to send lung sounds to the physician	38 (84)	3 (7)	3 (7)	0 (0)	1 (2)
Would recommend the app to others	38 (84)	5 (11)	1 (2)	0 (0)	1 (2)

Discussion

Principal Results

To our knowledge, this is the first study to assess the feasibility and acceptability of parents using a smartphone built-in microphone to capture lung sounds.

We found similar results when comparing the proportion of parents' quality recordings (266/346, 76.9%) with the proportion of physicians' quality recordings in this study (253/297, 85.2%) and that in a study by Ferreira-Cardoso et al [9] (73%). The same could be said for recordings with adventitious sounds; the proportion of parents' recordings with adventitious sounds (31/266, 11.7%) was similar to the proportion of physicians' recordings with adventitious sounds in this study (34/253, 13.4%) and that in the study by Ferreira-Cardoso et al [9] (14%).

Naturally, we attributed some of the differences in quality and adventitious sound proportion to the fact that the instructions on how to use the app were brief and the fact that parents were inexperienced and therefore misplaced the smartphone, pressed too gently, or even moved the smartphone or talked during the recordings.

Lung sounds were also recorded in a quiet but not soundproof room in the hospital. Therefore, the measured lung sounds might have been contaminated by ambient noise. However, with regard to the good overall agreement and moderate interrater reliability for the presence of adventitious sounds, the results were almost equal for recordings from physicians and parents and were similar to what has been reported in other studies [9,17].

With this study, we have confirmed the feasibility of using the AIRDOC app to record lung sounds with quality, as most participants had at least 1 recording with quality per location when recordings were acquired by physicians (30/45, 67%) and when they were acquired by parents (27/45, 60%). The results of our study are consistent with those of previous studies in which lung sound recordings were classified by experts [9,17,19]. For instance, the fact that recordings taken at the trachea have shown greater proportions of agreement (99%) and greater proportions of quality lung sounds (99%) has also been documented [9] and might be attributable to sounds having higher frequencies at this location, as the trachea has fewer tissues, which results in less filtering of sound signals [20,21]. These characteristics suggest that the trachea may be one of the best locations for the parental monitoring of respiratory status in real life. However, future studies with larger samples need to clarify whether adventitious sounds heard in the trachea are of clinical relevance for timely shared decisions. In adult patients with chronic obstructive pulmonary disease, sounds from this location could be used to predict exacerbations 5 days in advance [22].

Although only 13.4% (34/253) and 11.7% (31/266) of the physicians' and parents' recordings, respectively, had an identifiable adventitious sound, the percentage of participants with at least 1 lung sound recording with adventitious sounds (19/45, 42%) was similar to those found in previous works (35% in the study by Ferreira-Cardoso et al [9] and 28% in a study by Aviles-Solis et al [23]). The presence of adventitious sounds in the children without chronic respiratory diseases could be attributed to respiratory infections, as the recordings were made during the season with the highest incidence of respiratory infections. In addition, some of these participants were being followed up in the outpatient department due to a suspicion of a respiratory disease that had not yet been established, even though the presence of adventitious sounds has also been documented in healthy people [24,25]. The small difference between the presence of adventitious sounds in physicians' recordings and that in parents' recordings could be explained by the fact that the auscultations occurred some minutes apart rather than simultaneously (ie, the respiratory cycles differed among recordings) [26], which is a limitation of our study and should be addressed in further studies.

Although the parents' contact with the app was brief, they provided positive feedback on the auscultation feature with regard to its ease of use and their willingness to use it as a tool for communicating with the physician. Features related to an app's interface (eg, reduced number of screens and limited manual data entry) and communication with the health care team are among the features that are most valued by patients [27]. Parents' willingness to recommend the app to others was also high and similar to what has been reported in previous studies of asthma apps [28,29]. These findings are encouraging for the continued development of the AIRDOC app.

Limitations

This study has some limitations that need to be acknowledged. The results obtained from parents' recordings may not be generalizable to the real-life use of the app. Parents' performance in recording lung sounds was influenced by the fact that they were able to watch a demonstration of the procedure by observing physicians beforehand, and during parents' performance, physicians were able to give advice (how to press the smartphone, how to hold the smartphone, and no talking). However, the AIRDOC app is being developed for monitoring purposes in personalized follow-up care; therefore, demonstrations are being planned for parents. Another possible limitation was the use of the physicians' smartphones by the parents. We were aware of the possible effects of using an unfamiliar device; however, the decision to avoid the time-consuming process of installing the app on parents' smartphones was made, considering the internet connectivity limitations in the outpatient department. Additionally, comparing the smartphone auscultations performed by parents and physicians who used the same device allowed us to avoid the effects of differences among various embedded microphones. In the future, the feasibility of parents using the app should be evaluated in real life, with parents using their smartphones outside the clinical context. For this purpose, clear instructions on how to perform the auscultations should be made available in the app. With older children, we could have tested the self-recording of lung sounds, as they were old enough to manage their own diseases and treatment plans, but this would have increased the duration of the procedure, and it should be noted that data collection took place during routine medical visits. The self-recording of lung sounds by older children should however be carried out in further studies. Furthermore, the classification of adventitious sounds was based on broad classes (crackles and wheezes), without an attempt to distinguish subtypes, such as coarse crackles, fine crackles, high-pitch wheezes, and low-pitch wheezes. This decision was made in light of previous agreement studies, which showed that a broad classification was more reliable among experts than more detailed descriptions. We recognize that adventitious sound features are relevant to clinical decision-making, but it is sometimes very difficult for the human ear to discriminate these features [17]. The development of automated lung sound analysis methods will help us to overcome this limitation [30]. In addition, the proportions of recordings with crackles and recordings with wheezes were not analyzed separately; instead, our results are based on the proportions of recordings with adventitious lung sounds. This strategy was related to the small sample size and the small proportion of adventitious sounds (ie, crackles) in the recordings. The small sample size also hindered the comparison of smartphone auscultation performance among diagnosis groups; therefore, the project will continue to recruit children to strengthen the current findings. Another limitation is that other factors that may have been assessed by the physicians during the medical visits, such as respiratory rate, thoracic perimeter, and abdominal perimeter, were not included in our data collection. These parameters may be related to lung sound features and should be considered in the future.

Conclusions

The main findings suggest that lung auscultation via a smartphone built-in microphone is feasible when performed by parents, as they can record lung sounds with quality and can successfully capture adventitious sounds. This study also shows that parents are willing to use this technology in real life to provide feedback to physicians. Thus, smartphone lung auscultation can potentially be performed by parents to monitor children's respiratory status in real life. Additional research is needed to develop this technology further.

Abstract

Background: Admission to the neonatal intensive care unit (NICU) is costly and has been associated with financial and emotional stress among families. Digital health may be well equipped to impact modifiable health factors that contribute to NICU admission rates.

Objective: The aim of the study is to investigate how the use of a comprehensive prenatal digital health platform is associated with gestational age at birth and mechanisms to reduce the risk of admission to the NICU.

Methods: Data were extracted from 3326 users who enrolled in a comprehensive digital health platform between January 2020 and May 2022. Multivariable linear and logistic regression models were used to estimate the associations between hours of digital health use and (1) gestational age at birth and (2) mechanisms to reduce the risk of a NICU admission. Multivariable logistic regression models estimated the associations between (1) gestational age at birth and (2) mechanisms to reduce the risk of a NICU admission and the likelihood of a NICU admission. All analyses were stratified by the presence of any gestational conditions during pregnancy.

Results: For users both with and without gestational conditions, hours of digital health use were positively associated with gestational age at birth (in weeks; with gestational conditions: β=.01; 95% CI 0.0006-0.02; *P*=.04 and without gestational conditions: β=.01; 95% CI 0.0006-0.02; *P*=.04) and mechanisms that have the potential to reduce risk of a NICU admission, including learning medically accurate information (with gestational conditions: adjusted odds ratio [AOR] 1.05, 95% CI 1.03-1.07; *P*<.001 and without gestational conditions: AOR 1.04, 95% CI 1.02-1.06; *P*<.001), mental health management (with gestational conditions: AOR 1.06, 95% CI 1.04-1.08; *P*<.001 and without gestational conditions: AOR 1.03, 95% CI 1.02-1.05; *P*<.001), and understanding warning signs during pregnancy (with gestational conditions: AOR 1.08, 95% CI 1.06-1.11; *P*<.001 and without gestational conditions: AOR 1.09, 95% CI 1.07-1.11; *P*<.001). For users with and without gestational conditions, an increase in gestational age at birth was associated with a decreased likelihood of NICU admission (with gestational conditions: AOR 0.62, 95% CI 0.55-0.69; *P*<.001 and without gestational conditions: AOR 0.59, 95% CI 0.53-0.65; *P*<.001). Among users who developed gestational conditions, those who reported that the platform helped them understand warning signs during pregnancy had lower odds of a NICU admission (AOR 0.63, 95% CI 0.45-0.89; *P*=.01).

Conclusions: Digital health use may aid in extending gestational age at birth and reduce the risk of NICU admission.

Introduction

In the United States, most newborns who are born prematurely (before 37 weeks, 0 days gestation), with low birth weight (<2500 g), or with a health condition requiring special care are admitted to the neonatal intensive care unit (NICU) [1]. In 2022, approximately 9.5% of all infants born in the United States were admitted to the NICU [2]. NICUs are essential, as they improve infant survival and reduce morbidity for premature and sick infants [3]. However, admission to the NICU is costly and has been associated with financial and emotional stress among parents [4,5]. The parent-infant separation and parental stress resulting from NICU admission have been associated with poor maternal-infant attachment [6], lower breastfeeding rates [7], and higher rates of postpartum depression and anxiety [8], all of which may compromise subsequent pediatric health and development.

Several risk factors at the maternal level contribute to a higher likelihood of premature birth, which in turn increases the risk of NICU admission [9-11]. Primary maternal risk factors for a NICU admission include advanced age, chronic disease, substance use, preeclampsia, and peripartum infection [12-14]. Further, maternal stress, anxiety, and depression during pregnancy are associated with low birth weight and preterm birth [15-17]. At the institutional level, otherwise healthy infants who are born at hospitals with a high number of NICU beds have an increased likelihood of a NICU admission [10,18].

Previous interventions have successfully reduced the likelihood of a NICU admission with programs centered around increased patient education, access to care, and care coordination [19-21]. Digital health, including telemedicine and mobile apps, is increasingly used during pregnancy and may help address current gaps in prenatal care education by making pregnancy services more accessible and affordable [22,23]. By providing care coordination, continuous access to health care providers, and pregnancy-related educational materials, digital health may be well equipped to impact modifiable factors that contribute to NICU admission rates, including disease and mental health management.

In this study, we use data from Maven, a digital health platform, to explore how the use of a prenatal digital health platform that provides access to educational materials, telehealth through care providers, and care coordination is associated with gestational age at birth and mechanisms that may mitigate the risk of a NICU admission. First, we aimed to investigate the association between digital health use with gestational age at birth and mechanisms that could reduce the risk of a NICU admission (ie, mental health management and pregnancy education). Second, we explored whether gestational age at birth and the mechanisms to reduce risk are associated with a decreased likelihood of a NICU admission.

Methods

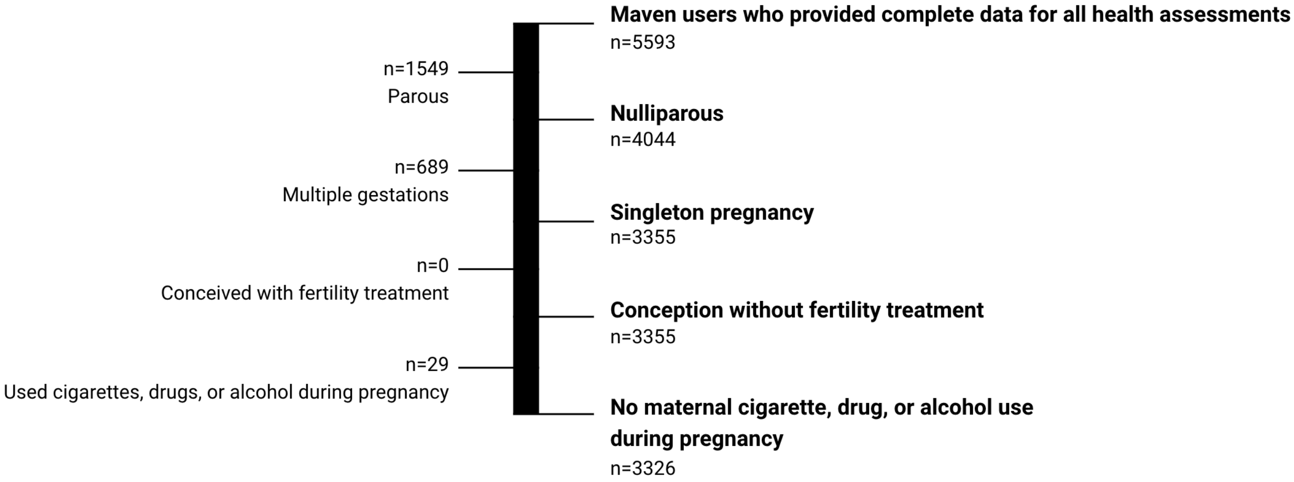
Ethical Considerations

All users consented to the use of their deidentified data for scientific research upon creating a Maven account. This study used deidentified data only, and the protocol was designated as exempt by WCG IRB (waiver 45 CFR § 46.104(d)(4)), an independent ethical review board.

Study Setting and Design

This retrospective cohort study examined the associations between digital health use and NICU admission among pregnant individuals enrolled in Maven. Maven is a comprehensive digital health platform designed to support women’s and family’s health and complement routine prenatal care. Users receive free and unlimited access to Maven as an employer or health plan–sponsored benefit through their own or their partner’s employer. Maven provides a range of digital health education and support services within its platform. Users have access to a care advocate—an allied health professional such as a nurse or social worker—who serves as their primary point of contact within the platform. This advocate helps coordinate digital prenatal services and directs users to relevant providers and resources. Additionally, within the platform, users have access to articles, videos, live classes, and appointments with providers across a variety of specialties, including obstetrics and gynecology, mental health, nutrition, and others. This analysis used both platform-use data and user-reported data from the enrollment questionnaire (completed during pregnancy upon enrollment in Maven) and the postbirth questionnaire (completed after birth). Together, the enrollment and postbirth questionnaires collected data on user demographics, health characteristics, pregnancy outcomes, and the impact of the digital health platform during pregnancy. Data were extracted from 5593 Maven users in the United States who enrolled in Maven’s pregnancy program and completed both health questionnaires between January 1, 2020, and May 27, 2022 (Figure 1). We excluded users who had previously given birth (n=1549), had a multiple pregnancy (n=689), conceived with fertility treatment (n=0), or reported any cigarette, drug, or alcohol use during pregnancy (n=29). These exclusion decisions were made due to the strong associations between experiences in a previous pregnancy or birth [24], multiple gestation [25], and drug or alcohol use with NICU admission [26], independent of other factors.

Figure 1. Flowchart of the users included in the current analysis.



Outcome: NICU Admission

The primary study outcome was the birthing parent report of a NICU admission on the postbirth questionnaire. After birth, users were asked “Did you experience any of the following complications during delivery?” and could select all that apply from a list of complications. Any users who selected “My baby went to the NICU” were considered to have a NICU admission in this analysis.

Hours of Maven Use

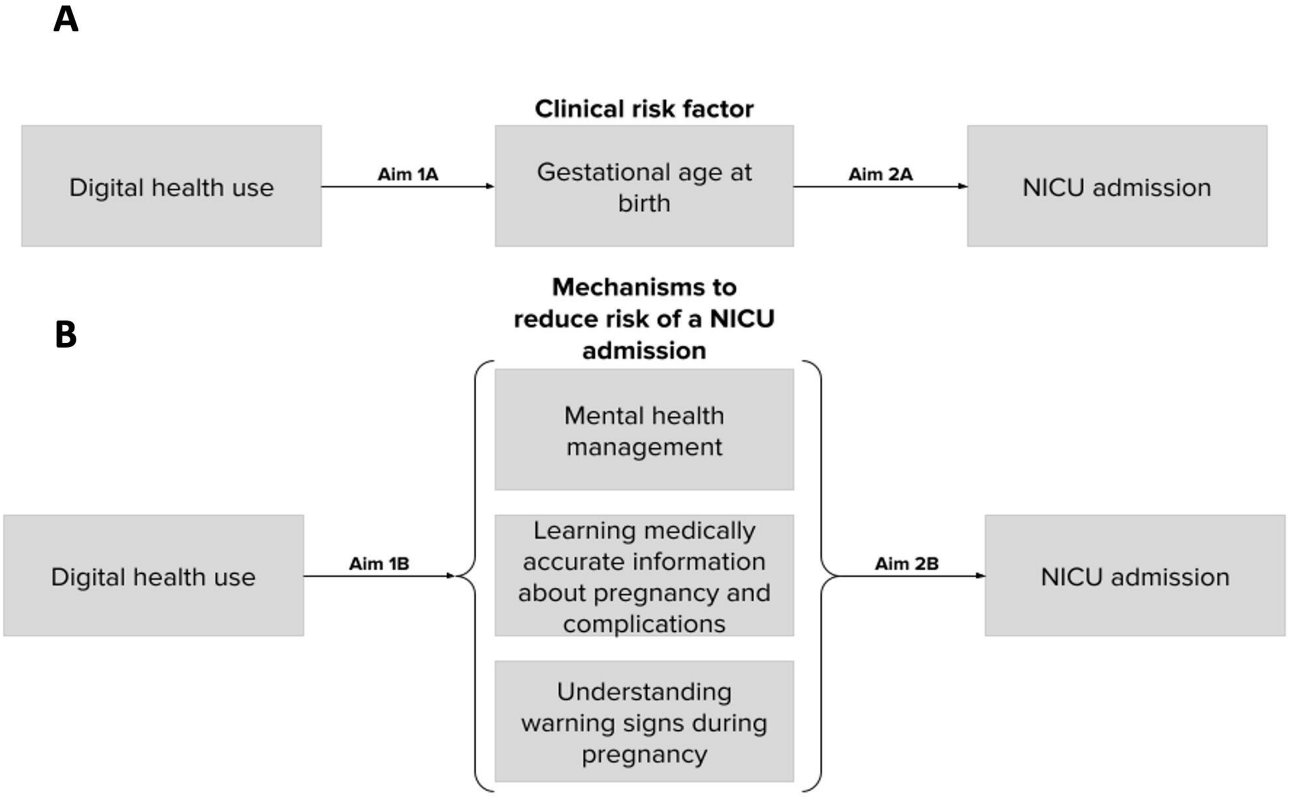
Hours of Maven use was the primary exposure in this analysis. The total number of active hours that each user spent on Maven was calculated from use data (automatically tracked within the platform) by summing the time spent with a care advocate, with a provider, messaging a provider, reading papers, attending web-based classes, or watching class recordings.

Impacts of Digital Health Use

This analysis examined the association between time spent on the platform with gestational age at birth and 3 pathways by which digital health may reduce the risk of a NICU admission (Figure 2A and B). Gestational age at birth was a continuous variable calculated from the difference between the user-reported due date (collected on the enrollment questionnaire) and the user-reported baby date of birth (collected on the postbirth questionnaire).

The three mechanisms of NICU admission risk reduction were (1) mental health management, (2) learning medically accurate information about pregnancy and complications, and (3) understanding warning signs during pregnancy. Each of the mechanisms was assessed on the postbirth questionnaire. To assess mechanisms 1 and 2, users were asked “In what way did Maven influence your experience?” and could select all that apply from a list of ways Maven may have influenced their pregnancy, including “Maven helped me manage anxiety and/or depression” and “Maven helped me learn medically accurate information about pregnancy and complications.” If either of these options were selected, the item was coded as “yes,” and the items were coded as “no” if they were not selected. To assess mechanism 3, users were asked “Did Maven help you understand warning signs during pregnancy?” and users selected “yes” or “no.”

Figure 2. Conceptual model to explore the associations between digital health use and likelihood of an infant NICU admission. (A) Conceptual model to explore the associations between digital health use, gestational age at birth, and likelihood of an infant NICU admission. (B) Conceptual model to explore the associations between digital health use, mechanisms to reduce the risk of a NICU admission, and likelihood of an infant NICU admission. NICU: neonatal intensive care unit.



Gestational Conditions

Given the strong associations between gestational conditions and infant health outcomes [27], all analyses were stratified by the presence of gestational conditions. To capture information on conditions that developed both before and after enrollment into Maven, the following conditions were assessed on both the enrollment and postbirth questionnaires: cholestasis, gestational diabetes, intrauterine growth restriction, high blood pressure, preeclampsia, eclampsia, vaginal blood loss (nonlabor related), problems with the placenta, issues with the cervix, excess or diminished amniotic fluid, infant large for gestational age, perinatal mood disorder, or hemolysis, elevated liver enzymes, and low platelet count syndrome. If a user reported the presence of any of the above conditions during their current pregnancy, they were coded as “Had at least one gestational condition” versus “No gestational conditions.”

Covariates

Data from the enrollment questionnaire were used to create covariates. Ethnicity and race were categorized into “Hispanic or Latinx” and non-Hispanic or Latinx: “Asian or Pacific Islander,” “Black,” “White,” and “other” (comprised of users who reported their race as multiracial or American Indian. This category was created due to a small sample size of users who identified as multiracial or American Indian). To account for the societal and geographical factors that contribute to a NICU admission, we used the Centers for Disease Control and Prevention’s Social Vulnerability Index (SVI) [28]. SVI is a geographic measure of community vulnerability by using data from 4 domains: socioeconomic status, household composition and disability, minority status and language, and housing type and transportation. A continuous SVI score was assigned to each user based on their ZIP code, with an SVI closer to 1 representing high vulnerability. Chronic conditions were assessed as cumulative risk scores, calculated by adding the number of medical conditions reported by each user. Users reported their mode of birth (vaginal or cesarean) on the postbirth questionnaire.

Statistical Methods

We conducted descriptive analyses to explore user demographic and medical characteristics stratified by the presence of gestational conditions. Chi-square or Fisher exact tests were used to assess categorical variables, and 2-tailed *t* tests and Wilcoxon rank-sum tests were used to assess continuous variables.

Adjusted linear regression was used to assess the association between time spent on the digital health platform and gestational age at birth (Figure 2; aim 1A). Adjusted logistic regression was used for all other aims. For aims 1A and 1B (Figure 2), assessing the associations between time spent using the digital health platform, gestational age at birth, and the 3 mechanisms to reduce the risk of NICU admission (mental health management, learning medically accurate information during pregnancy, and understanding warning signs during pregnancy), each component was assessed as an outcome in its own model. For aims 2A and 2B (Figure 2), examining whether gestational age at birth and mechanisms to reduce NICU admissions are associated with the likelihood of a NICU admission, each of the 4 components was assessed as the primary exposure in its own model with a report of a NICU admission as the outcome. Adjusted regression models controlled for age, race and ethnicity, mode of delivery, chronic conditions, SVI, and the number of days enrolled in Maven. All models estimated the effect with 95% CIs, and significance was determined when *P*<.05. All statistical analyses were performed using RStudio (Posit Software, PBC).

Results

Sample Characteristics

Our analytic sample consisted of 3326 pregnant individuals enrolled in the maternity program on the digital health platform. The mean age of our sample was 32.3 (SD 3.89) years. In total, 22.5% (747/3326) of users identified as non-Hispanic Asian or Pacific Islander, 46.5% (1547/3326) as non-Hispanic White, and 14.3% (475/3326) preferred not to disclose their race and ethnicity status (Table 1). Relatively few users reported the presence of any chronic medical conditions, with thyroid disease being the most prevalent (248/3326, 7.5%). During pregnancy, high blood pressure (482/3326, 14.5%) and gestational diabetes (357/3326, 10.7%) were the most common gestational conditions reported. The mean infant gestational age at birth was 39.3 (SD 1.57) weeks. A total of 68.9% (1799/3326) of users reported the digital health platform helped them learn medically accurate information about pregnancy and complications, 59.7% (1912/3326) reported the platform helped them understand warning signs during pregnancy, and 13.8% (361/3326) reported the platform helped them manage their mental health. A majority of 70.8% (2354/3326) of users reported having a vaginal birth, and 10.6% (353/3326) reported their infant was admitted to the NICU.

Compared to users who did not develop any gestational conditions during their pregnancy, users who developed one1 or more gestational conditions were less likely to be non-Hispanic White (44.1% [nn=613/1390], 44.1% vs. 48.2%[nn=934/1936], 48.2%) and more likely to be older (32.8 years y vs. 32.0 years); obese (21.3% [nn=296/1390], 21.3% vs. 9.4%[nn=182/1936], 9.4%); and have a a history of type 1 or type 2 diabetes (2.2% [nn=30/1390], 2.2% vs. 0.2%[nn=3/1936], 0.2%), hypertension (5.5% [nn=77/1390], 5.5% vs. 0.2% nn=3/1936], 0.2%), thyroid disease (8.9% [nn=124/1390,]8.9% vs. 6.4% [nn=124/1936], 6.4%), anxiety (27.3% [nn= =379/1390], 27.3% vs. 18.5% [nn=359/1936], 18.5%), and depression (15.5% [nn=216/1390], 15.5% vs. 9.1% [nn=177/1936], 9.1%). Users with gestational conditions were more likely to report that the digital health platform helped them manage their mental health (15.9% [nn=177/1390], 15.9% vs. 12.3% [nn=184/1936, 12.3%]), deliver preterm (8.7% [nn=121/1390], 8.7% vs. 3.4% [nn=65/1936], 3.4%), have a baby who was admitted to the NICU (15.6% [nn=217/1390], 15.6% vs. 7.0% [nn=136/1936], 7.0%), and less likely to have a vaginal birth (62.7% [nn=872/1390], 62.7% vs. 76.5% [nn=1482/1936], 76.5%). The average amount of digital health use during pregnancy was 8.1 (SD 7.9) hours. Digital health use did not vary by the presence of gestational conditions.

[a] Data are displayed for users who enrolled in Maven Clinic and gave birth between January 1, 2020, and September 19, 2022.

[b] Not applicable.

[c] HELLP: hemolysis, elevated liver enzymes, and low platelets.

[d] NICU: neonatal intensive care unit.

Associations Between Digital Health Use, Gestational Age at Birth, and Mechanisms to Reduce Risk of a NICU Admission

In analyses of users who did not develop any gestational conditions during pregnancy, adjusted models revealed that for every 1-hour increase in digital health use, users experienced an increase in gestational age by 0.01 weeks (β=.01; 95% CI 0.0006-0.02; *P*=.04); a 9% increase in their odds of understanding warning signs during pregnancy (adjusted odds ratio [AOR] 1.09, 95% CI 1.07- 1.11; *P*<.001); a 3% increase in their odds of reporting that the platform helped the user manage their mental health (AOR 1.03, 95% CI 1.02-1.05; *P*<.001); and a 4% increase in their odds of reporting that the platform helped the user identify medically accurate information (AOR 1.04, 95% CI 1.02-1.06; *P*<.001; Table 2).

In analyses of users who developed 1 or more gestational conditions during pregnancy, adjusted models revealed that for every 1-hour increase in digital health use, users experienced an increase in gestational age by 0.01 weeks (β=.01; 95% CI 0.0006-0.02; *P*=.04), an 8% increase in their odds of understanding warning signs during pregnancy (AOR 1.08, 95% CI 1.06-1.11; *P*<.001), a 6% increase in their odds of reporting that the platform helped the user manage their mental health (AOR 1.06, 95% CI 1.04-1.08; *P*<.001), and a 5% increase in their odds of reporting that the platform helped the user identify medically accurate information (AOR 1.05, 95% CI 1.03-1.07; *P*<.001).

Table . Associations between hours of digital health use, gestational age at birth, and mechanisms to reduce risk of a neonatal intensive care unit admission[a].

[a] Adjusted for age, Social Vulnerability Index, mode of delivery, race and ethnicity, chronic conditions, and days on Maven.

[b] AOR: adjusted odds ratio.

Associations Between Gestational Age at Birth, Mechanisms to Reduce Risk of a NICU Admission, and the Likelihood of a NICU Admission

In analyses of users who did not develop any gestational conditions during pregnancy, adjusted logistic regression models found that for every 1-week increase in infant gestational age at birth, users experienced a 41% reduction in the odds of their infant being admitted to the NICU (AOR 0.59, 95% CI 0.53-0.65; *P*<.001; Table 3). Understanding warning signs during pregnancy (*P*=.05), learning medically accurate information about pregnancy and complications (*P*=.33), and mental health management (*P*=.83) were not significantly associated with the odds of a NICU admission at birth.

Table . Association between gestational age at birth, mechanisms to reduce risk of neonatal intensive care unit (NICU) admission, and the likelihood of a NICU admission[a].

	0 gestational conditions (n=1936)		≥1 gestational conditions (n=1390)	
	Adjusted odds ratio of a NICU admission (95% CI)	*P* value	Adjusted odds ratio of a NICU admission (95% CI)	*P* value
Gestational age at birth (weeks)	0.59 (0.53-0.65)	<.001	0.62 (0.55-0.69)	<.001
Understanding warning signs during pregnancy	0.73 (0.53-1.01)	.05	0.63 (0.45-0.89)	.01
Learning medically accurate information	1.22 (0.83-1.83)	.33	0.92 (0.61-1.42)	.71
Mental health management	0.95 (0.56-1.52)	.83	1.45 (0.83-2.42)	.17

[a] Adjusted for age, Social Vulnerability Index, mode of delivery, race and ethnicity, chronic conditions, and days on Maven.

In analyses of users who developed 1 or more gestational conditions during pregnancy, adjusted logistic regression models found that for every 1-week increase in infant gestational age at birth, users experienced a 38% reduction in the odds of their infant being admitted to the NICU (AOR 0.62, 95% CI 0.55-0.69; *P*<.001; Table 3). Additionally, users who reported understanding warning signs during pregnancy experienced a 37% reduction in the odds of their infant being admitted to the NICU (AOR 0.63, 95% CI 0.45-0.89; *P*=.01; Table 3). Learning medically accurate information about pregnancy and complications (*P*=.71) and mental health management (*P*=.17) were not significantly associated with the odds of a NICU admission.

Discussion

Principal Results

The results of this retrospective cohort study suggest that the use of a comprehensive digital health platform during pregnancy helps users with and without gestational conditions extend their gestational age at birth, learn medically accurate information, manage their mental health, and identify warning signs during pregnancy. For all users, an increase in gestational age at birth was associated with a decreased likelihood of a NICU admission. Additionally, among users who developed 1 or more gestational conditions during pregnancy, those who reported that the digital health platform helped them identify warning signs during pregnancy had a 37% reduction in the odds of their infant being admitted to the NICU.

Comparisons With Prior Work

Studies have found that birth outcomes can be improved through resources that support and complement traditional prenatal care. Previously, these influential resources have involved care coordination, transportation to appointments, and education [19-21]. Similarly, digital health can provide continuous care coordination and increased access to providers and educational materials [29]. This type of continuous support has been shown to have several benefits: improving in-clinic conversations with providers, influencing one's mode of delivery and birth plan [30,31], managing mental health throughout pregnancy [32], and enabling users to identify and address problems immediately (vs waiting until their next in-person appointment) [33]. Additionally, digital health provides a patient-centered approach to complement routine prenatal care throughout pregnancy [34]. While routine prenatal care is limited by time constraints and other clinical needs of each visit, digital health is especially equipped to provide patient education and offer individualized content that may address patient concerns between in-person appointments [35]. In our study, using a digital health platform was linked to mental health management, learning medically accurate information, and understanding warning signs during pregnancy. Additionally, understanding these warning signs was associated with a reduced likelihood of NICU admission. While mental health management and learning medically accurate information about pregnancy were not associated with NICU admission, improvement in perinatal mental health and education may still be important in mitigating the risk of adverse obstetric outcomes including NICU, and these factors should continue to be investigated in future work.

In our sample, higher levels of digital health use were associated with an increase in gestational age at birth. It is important to note that while statistically significant, our effect size is quite small. For every 1 hour of digital health use, we saw an increase in gestational age by 0.01 weeks (approximately 2 hours). While the effect itself is small, identifying any signal is encouraging, given that an increase in gestational age decreases the risk of preterm birth and related complications, including a NICU admission [1]. This finding is consistent with previous research, which has shown that among pregnant individuals with gestational conditions, access to telehealth care is associated with a decreased likelihood of preterm birth [36,37]. Our results are especially promising because in this sample, digital health use was self-directed by the users. While the digital health platform offered resources and services aimed at reducing the risk of NICU admission, users were not given instructions on how frequently to use the platform and were not required to use specific types of care or resources. Future interventions with targeted protocols may yield even greater impacts.

Among users with 1 or more pregnancy-related conditions, users who reported that the digital health platform helped them understand warning signs during pregnancy had a reduced likelihood of a NICU admission. Given the rapid changes that occur as a pregnancy progresses, a diagnosis of a clinical condition like gestational hypertension or diabetes in an otherwise healthy individual may yield questions or concerns that arise outside of a monthly prenatal care appointment [34,38]. Digital health platforms can offer access to providers as well as educational content to help users manage their diagnosis outside of traditional in-person care [39,40].

Limitations

Limitations of this study should be considered. First, our study population consisted primarily of commercially insured individuals who had internet access on a smartphone device or computer. Second, the majority identified as White and non-Hispanic, potentially limiting the generalizability and scalability of these findings.

Conclusions

Digital health use may aid in reducing the risk of a NICU admission by extending gestational age at birth and helping individuals recognize warning signs during their pregnancy. As the use of digital health during pregnancy increases, this model of care may serve as a blueprint for how digital services may contribute to disease management during pregnancy and improve birth outcomes.

Acknowledgments

The authors are grateful to Maven users for using the application and providing the data analyzed in this research.

Abstract

Background: Disruptive behavior disorders are among the most common disorders of childhood, and evidence-based parenting programs are the first-line treatment. Digital microinterventions have been proposed as one possible means of supporting parenting style change by giving parents in-the-moment advice about how to respond to challenging behavior. Until now, no digital microintervention supporting evidence-based parenting skills programs has been evaluated.

Objective: The aim of this study is to evaluate the subjective experience of parents using a digital microintervention to support evidence-based parenting skills, with particular attention to acceptability, usability, family relationships, and parents' values.

Methods: We conducted serial interviews with 11 parents of 33 children before and after spending 3 weeks using an app including 3 digital microinterventions. Parents were recruited via local authorities in the Midlands region of the United Kingdom. Previous participation in a parenting program was an inclusion criterion. Interviews explored family composition; child behavior problems; and experience of using the mobile app, including barriers to use. Thematic analysis was conducted from a user-centered design perspective, and illustrative case vignettes were produced.

Results: Many parents used the app in ways that helped them rather than strictly following the instructions they were given. Parents described a range of barriers to using the app including practical problems and failure to change child behavior. Parents and children responded in a variety of ways to the use of the phone, with many wholeheartedly embracing the convenience of technology. Case vignettes illustrate the uniqueness of each family's experience.

Conclusions: Parents' use of a mobile app supporting evidence-based parenting skills is difficult to predict due to the unique challenges each family encounters. Many parents found it an acceptable and helpful addition to family life, but increased personalization is likely to be key to supporting parents. Future digital microintervention developers should keep in mind that parents are likely to use the app pragmatically rather than following instructions, may struggle to use a complex app under pressure, and are likely to hold complex feelings about parenting with an app.

Introduction

Disruptive behavior disorders such as conduct disorder and oppositional defiant disorder are among the most common mental health conditions of childhood [1]. Untreated children with conduct disorder persistently violate the rights and boundaries of other children as well as adults [2]. Although phenotypes vary, young people presenting with some of the criteria for conduct disorder are at high risk for future mental illness, educational failure, and contact with the criminal justice system [3-5].

This study evaluated an app that was designed to help parents to use evidence-based parenting skills (including praise, age-appropriate time-out, and relaxation exercises), which are shown to improve children's behavior problems such as angry outbursts, violence, and refusing to follow instructions.

Evidence-based parenting skills programs are the first-line treatment for disruptive behavior disorders according to the National Institute for Health and Care Excellence [6]. Triple P, Incredible Years, and Chicago Parenting Program are supported by evidence from systematic reviews and meta-analyses. Changes in parenting style can lead to children building stronger self-esteem and learning to understand and respond to limits [7,8]. These programs can have long-term benefits; randomized controlled trials have shown that they set children on a path for better relationships, reduced criminal activity, and fewer behavioral diagnoses up to 8 years later [9].

Incredible Years, Triple P, and Chicago Parenting Program tend to draw on a range of didactic approaches to equip parents with new skills. The programs are frequently run as groups with 6 - 12 parents meeting weekly for 3 or 4 months, during which time, they use roleplay, videos, and group discussions to learn new skills [10]. Programs generally begin by supporting parents to improve their relationship with their child through positive play and showing warmth before moving to equip parents with proportionate and effective approaches to setting limits such as ignoring unwanted behavior, distracting the child, and introducing natural or logical consequences.

This paper focuses on 3 particular skills. The first is praise: praising a child's successes is an important part of building self-esteem, but vague praise of children with low self-esteem or, worse, backhanded praise, can damage the parent-child relationship [11]. The second is mindfulness: learning to calm raised emotions is a valuable skill for children with behavior problems, but there is a limited emotional window where children are responsive to mindfulness [12]. The third is a skill called "time-out" in Incredible Years and "quiet time" in Triple P, which provides an effective means of setting limits when carried out correctly. However, parents often struggle to use this skill, and resources available on the web conflict with the evidence for an effective time-out [13].

Changing parent behavior remains a significant challenge. One important consideration is that children's behavior often begins to get worse as parents introduce evidence-based parenting techniques, so-called "extinction bursts," which can wrongly give parents the impression that the techniques are not working [14]. A systematic review of face-to-face parenting programs for disruptive behavior found that only half of parents who start programs finish them [15].

The advice offered on apps and websites sometimes runs contrary to the evidence [13,16]. Although online programs provide an alternative to face-to-face programs, engagement appears to be even lower than in face-to-face programs, and evidence of lasting behavior change is weaker [17,18]. Extinction bursts are one reason for poor engagement: worsening behavior means parents lose faith in the program and quit. One parenting skills practitioner described to us the period between parental behavior change and child behavior improvement as the "giving-up gap." At the same time, many parents fail to implement parenting techniques learned in a calm classroom once they are in a hectic home environment. This is in keeping with Loewenstein's concept of the hot-cold empathy gap: in a calm state, people struggle to imagine the challenges they will face when they are emotionally aroused [19].

Given these 2 challenges, it is worthwhile considering whether more engaging digital interventions could change behavior. Baumel et al [20] called for digital microinterventions to help parents achieve change in parenting style and downstream improvements for parents. They define digital microintervention as "highly focused interventions delivered in the context of a person's daily life with little burden on the individual" [20]. Parents report lacking free time and having limited cognitive bandwidth for learning new skills, and as such, immediate interventions with little burden have great potential [21]. Digital microinterventions have the potential to address the giving-up gap by helping parents notice their achievements and overcome the hot-cold empathy gap by giving guidance in the heat of the moment.

Despite Baumel et al's [20] call to action, several unknowns remain. The cognitive constraints parents face may make an app overwhelming or may make prompts on an app particularly useful. Parents may prefer not to use a digital device to support parenting or may find it convenient. Parents may find that they prefer comprehensive instructions on parenting rather than a highly focused intervention. No digital microintervention has previously been used to guide parents through evidence-based skills in the moment when children are displaying disruptive behaviors.

In this paper, we aimed to evaluate the subjective experience of parents using a digital microintervention to support evidence-based parenting skills, with particular attention to acceptability, usability, family relationships, and parents' values.

Methods

Context and Target Population

Participants were recruited through several parenting programs run by local authorities across the Midlands region of the United Kingdom. Recruitment was supported by parenting program practitioners who advertised the study by emailing the study invitation to parents who had recently completed a program or by directly inviting parents who attended their final sessions. Others were recruited by word of mouth around the local authority. A participant information leaflet was shared with interested parents. We aimed to establish a sample of 10 participants in keeping with other recent pilots of parenting apps and following the 10±2 rule in usability testing [22,23]. Included parents were aged 18 years and older and had a child aged 2 - 10 years. Parents were included if they had sufficient concerns about their child's behavior to be referred to a parenting skills program. By only including parents who had previously benefited from a parenting skills program, we ensured that they had received support with the basic components of parenting skills. The intervention is intended for use by parents who have attended a parenting skills program so this inclusion criterion was essential to the external validity of the intervention. Parents were excluded if they did not have an Android or iOS smartphone, which could use the app.

Intervention

We previously developed a mobile app for iOS and Android through an iterative coproduction process involving 42 parenting skills practitioners reported elsewhere [24]. This app guided parents through using praise, mindfulness, and time-out or quiet time. It guided parents through using praise with a list of scrollable images with simple instructions on them. It guided parents through mindfulness by including a visual graphic helping children use "box breathing" as well as a guide walking parents through using a sensory grounding technique [25].

Procedures

Each participant was interviewed twice in order to develop a rich understanding of how the digital microintervention fitted into family life [26]. At interview 1, participants completed a consent form, were offered a participant information form, and had the opportunity to ask any questions about the research. Then, they answered questions about their family composition, parenting style, and experience of parenting skills. They also talked about their child's behavior problems and the strategies they use to manage these. Then, they were given a tour of the app and supported to download it to their own mobile device. They were asked about their initial responses to the app, including which features they thought could be useful or unhelpful. Topic guides are reported in Multimedia Appendix 1.

When they were shown the app, little specific psychoeducation was delivered, as they had already attended a parenting program. However, the app included suggestions to only use time-out or time in under circumstances of oppositional behavior or violence in keeping with best practice. Parents were encouraged to use the mindfulness activities with and without their children as they wished. They were encouraged to review the praise guidance, which offered very simple prompts to praise children frequently.

At the end of interview 1, participants received a US $32 shopping voucher and were invited to use the app and book a second interview about 3 weeks later following similar app pilots [27,28]. At interview 2, parents were asked whether they had used the app and how they had found the experience. Parents were prompted to talk about any features they had found helpful and any problems they had encountered. The whole incentive for participating was given during interview 1 to make it easier for parents to exit the study if they wished to.

All interviews were conducted remotely by NH and CT via Microsoft Teams or WhatsApp Voice Call and recorded with consent. All interviews were audio recorded and transcribed. If participants wished to have a friend or family member present during the interviews, this was accommodated. Transcripts were not returned to participants for comments.

Analysis

Analysis was conducted by NH and JLS. Thematic analysis was conducted using NVivo (version 1.5; Lumivero) and followed the principles set out by Braun and Clarke [29,30] using an inductive approach with a theoretical underpinning in user-centered design. Analysis was also informed by a narrative lens in order to develop a richer understanding of how the digital microinterventions had interplayed with the dynamic stories of the families because "narratives provide us with access to people's identity and personality" [31]. The narrative approach also helps present the uniqueness of each family's story. Both NH and JLS read and reread the data before generating initial codes and searching for themes. Themes were reviewed discursively and named by NH. The coding framework is given in Table 1 and findings are discussed in detail below.

Table . Coding framework and illustrative quotations.

Themes		Representative quotations
Theme 1: Unexpected uses of the app		
	1.1: Different children	“I only tried it twice in my 10 year old cause I found he got more annoyed. I probably used it about five times with my 4 year old.”
	1.2: Learning the app	“I spent the next day like on the app, seeing what was on there and stuff”
	1.3: Different timers	“I’ve just remembered what it said and it’s like if it’s three minutes, or whatever, I’ve just put on my Google (dot)”
	1.4: Specific contexts	“I’ve used it generally every night, before she goes to bed, with my little one. We do a little bit of breathing to like, calm down”
Theme 2: Not using the app		
	2.1: Phone unavailable	“It’s been hard if my phones dying of battery”
	2.2: Forgetting	“I think it’s remembering in the moment to actually pick up my phone and think to use it when it’s happening.”
	2.3: Urgency	“I don’t know if you’re able to do voice activation or just an easier way to access those particular parts where you need them in that moment.”
	2.4: Not getting good results	“He got put in time out cause he’d hit me and he’d hit his younger brother. And I had to keep putting him back in time out, like because he kept going. And I kept making him sit. But like even after the time he just, he was just really upset.”
Theme 3: Parenting with a mobile app		
	3.1: Surprised by mobile parenting	“Before I knew about this, I never even considered there would be an app for this sort of thing”
	3.2: Using a phone is inappropriate	“I have issues as a professional with electronics and devices and as a parent and I can limit it, but in this case I don’t see it as a problem”
	3.3: Phones are helpful and convenient	“It’s not a distraction. it’s a useful tool to have”

Full transcripts include extensive personal content relating to children so they are not presented. Instead, anonymized brief narrative case studies illustrate the individuality of each included family. Each relates to a specific interviewee and draws together examples of their family life. Two brief case studies are presented in the *Results* section (see Multimedia Appendix 2 for others). The results were presented in keeping with the COREQ (Consolidated Criteria for Reporting Qualitative Research) [32].

Ethical Considerations

Ethics approval was obtained from the Biomedical and Scientific Research Ethics Committee at the University of Warwick (BSREC 34/22 - 23). Informed consent was obtained from all participants, and data were anonymized.

Research Team and Reflexivity

NH and CT conducted the interviews, and participants were aware that NH was a psychiatrist with experience supporting parents concerned about their children’s behavior and well-being. Participants were referred to the research from a trusted source, the parenting team already supporting them, so participants may have expected the digital microintervention to be useful. NH and CT therefore actively sought to draw out the problems with the digital microintervention, but 2 participants nevertheless made apologetic comments including “I’m not saying that this is any reflection on the app at all” and “I looked through it like last night just kind of to refresh it. I wouldn’t say I look at it every, like every day.” When participants made comments along these lines, they were reminded that the aim of the research was to identify any problems, not just strengths.

The analysts who contributed to the thematic analysis and editing of the brief case studies, PW and JLS, had limited previous contact with these particular families but were involved in developing the app so they contributed a more technology-focused perspective than NH. DG was not directly involved in data collection or analysis or software development so he provided a different set of perspectives.

Results

Participants

Overview

In total, 11 parents of 33 children were included. All were female, and all had at least 1 child aged 2 - 10 years. Among the participants' 33 children, 1 was 18 years, and 6 others were 10 years and older. One was younger than 2 years. Only 1 was an only child. All used social media, most commonly Instagram, Facebook, and WhatsApp. Table 2 gives the characteristics of the included parents.

On average, interview 1 lasted 38 minutes and 42 seconds, and interview 2 lasted 21 minutes and 8 seconds. One participant did not attend a second interview and did not give a reason. All 10 parents who attended interview 2 reported that they had used the app in some form.

Table . Characteristics of included parents.

Topic	Parents (N=11), n (%)
Parents with more than 1 child	10 (91)
Any child with autistic spectrum disorder or attention-deficit/hyperactivity disorder	4 (36)
Use of time-out or naughty step or quiet corner	10 (91)
Past use of parenting app	2 (18)
Past use of parenting books	4 (36)
Use of social media	11 (100)
Lived with partner	7 (63)

Parenting Skills Background

Four children had diagnoses of attention-deficit/hyperactivity disorder or autistic spectrum disorder. Four participants were the only adults living at home. In total, 4 had used parenting books in the past, but only 2 had used a parenting app before. Only 1 had never used any variant of time-out or quiet time.

Participants reported a range of techniques or methods they took to managing behavioral and emotional problems prior to being offered the app. These included evidence-based techniques like distracting children, ignoring unwanted behavior, or using star charts. Some focused on managing emotions through calming breathing, coloring, or using an anger scale to notice when they are becoming upset. Other parents mentioned negative reinforcement through shouting, and one suggested other parents used corporal punishment. Encouraging physical touch was also identified as a useful emotion regulation technique, and predictable meal plans were important to another family. One parent mentioned using melatonin to manage behavior problems.

Comments Particular to This App

Reported strengths of the app including the mindfulness techniques and the advice on using praise, reducing excessive punishment, impulsivity, and inconsistency. They also approved of the prompts to remind parents to use positive parenting skills. They noted some weaknesses of the app including technical bugs, navigation difficulties, as well as the calming breathes being too slow for small children.

Thematic Analysis: Parents' Experience of Using a Parenting App

To address out main research question, we conducted a thematic analysis of the interviews in relation to parent's experience of using the app. Table 1 shows the coding framework.

Theme 1: Unexpected Uses of the App

Theme 1.1: Different Children

Parents reported that they had used the app with some children but not with others. This is certainly appropriate for parents with older or younger children, but parents even found that not all of their children in the age range 2 - 10 years had been responsive to the app. This ran contrary to our expectation that the app would increase consistency between children by supporting parents to use the same activities with all age-appropriate children. Several had tried the app with more than 1 child before deciding which one it was best suited to.

> *I've tried it once with (child 1) because she doesn't tend to get to a point where she needs it. Normally if I say to her "calm" it stops. It's more for (child 2) I've used it for the calming time which has worked quite nicely and I think he's liked it.* [Participant 4, interview 2]
>
> *I think I only tried it twice in my 10 year old cause I found he got more annoyed. I probably used it about five times with my 4 year old.* [Participant 9, interview 2]

Theme 1.2: Learning the App

Although we expected the app to be used as a digital microintervention in the heat of the moment, some parents used it as a way of learning instead. Some read the information and memorized the approaches to the problems. Others used it like a game to "play through" the possible problems and prepare a strategy. One parent described it as "almost like, you know, pretending to click through to the options to see what was behind it" [Participant 11, interview 2].

> *After our discussion, yeah, I spent the next day like on the app, seeing what was on there and stuff. And*

> *I was like. OK, that’s handy.* [Participant 9, interview 2]

The praise section was particularly well suited to being used for learning only and then applying the skills at another time. Although the app included prompts and reminders to use praise, many parents primarily read through the praise advice.

> *It’s like a slideshow of pictures and with some information and it’s regarding when to give children praise and there was a few other things on there, which I found was a really good read.* [Participant 2, interview 2]

Theme 1.3: Different Timers

Although parents used the mindfulness and praise advice as recommended, they often took the time-out information but used different timers around the home instead of the app’s built-in timer. Once they had learned how the app worked, some preferred to link it to a timer that their child could see as well or a timer in a different space in the house.

> *So I’ve just remembered what it said and it’s like if it’s three minutes, or whatever, I’ve just put on my Google and just been like “Ohh hey Google, set the timer for three minutes.”* [Participant 6, interview 2]

> *We have some egg timers and we have the ticking timers as well so I tend to use them anyway. So I wouldn’t necessarily use it on via the app. But if I was a parent who wasn’t already using the timers that I’ve got, then I think it was a good idea on the app.* [Participant 2, interview 2]

Theme 1.4: Specific Contexts

Some parents reported that they primarily used the app in particular settings. The mindfulness section was intended for parents to use with their child in a relaxed state so they would be prepared to apply the same skills in a difficult context. This may have been due to a change in the environment or a daily routine.

> *We’ve used it out and about we used it on holiday. We used it in the airport. We’ve used it like when we’ve been out in the car and things like that, and she’s getting really good at using it herself.* [Participant 10, interview 2]

> *I’ve used it generally every night, before she goes to bed, with my little one. We do a little bit of breathing to like, calm down and calm down function quick timer and she seems to like that.* [Participant 5, interview 2]

Theme 2: Not Using the App

Theme 2.1: Phone Unavailable

Some parents reported that they did not use the app because their phone was not in hand at the moment when they needed it. This was generally because it was somewhere else around the house, possibly on charge or being used by another child.

> *Maybe one of the kids is watching YouTube on the phone or like kids tube or whatever, so I can’t just take it off one of the other children because one of them’s misbehaving.* [Participant 6, interview 2]

> *It’s been hard if my phones dying of battery and stuff like that.* [Participant 9, interview 2]

Theme 2.2: Forgetting

Several parents reported forgetting to use the app. The app required a change of routine and parenting approach for them. Emotional and behavioral problems did not immediately trigger parents to pick up their phones.

> *I think it’s remembering in the moment to actually pick up my phone and think to use it when it’s happening.* [Participant 11, interview 2]

> *I think I could use it, but I just think I've forgotten about it and I just need to get it in my head to use it as a strategy more in the house as well.* [Participant 10, interview 2]

Theme 2.3: Urgency

Rather than interpreting their experience as “forgetting,” some parents reported that the situation had been too urgent for them to get their phones out. They described it as a rational and deliberate choice not to use the app in the heat of the moment. One parent suggested that a voice-controlled app would be easier to use when emotions are raised.

> *If (child 1) is hitting (child 2), I wouldn’t necessarily think “I’ve got go and get my phone” or “I’m gonna have to look at my phone at the app”, I’d just be like try and think about like what I need to do or try to manage the situation.* [Participant 6, interview 2]

> *I don’t know if you’re able to do voice activation or just an easier way to access those particular parts where you need them in that moment.* [Participant 2, interview 2]

Theme 2.4: Not Getting Good Results

Some parents did not use the time-out or quiet-time components because they did not achieve a change in behavior and because children were resistant. In some children, this was due to feeling that time-out was age-inappropriate, and in others, it was due to time-out being too difficult. There was no indication that children’s resistance was specifically linked to the app.

> *He got put in time out cause he’d hit me and he’d hit his younger brother. And I had to keep putting him back in time out, like because he kept going. And I kept making him sit. But like even after the time he just, he was just really upset.* [Participant 6, interview 2]

> *When my son was in a real mood he’d pick (a chair) up and, you know, smash it against a door or something.* [Participant 5, interview 2]

Theme 3: Parenting With a Mobile App

Theme 3.1: Surprised by Mobile Parenting

Some parents were surprised that they were being offered an app to help with parenting. They reported that some of their children were surprised to find their parents using an app to guide evidence-based parenting rather than entertainment. Although initially surprised by the app, they reported rapidly becoming used to the phone and seeing it as an implement, which parents could use well or not.

> *Before I knew about this, I never even considered there would be an app for this sort of thing.* [Participant 3, interview 1]
>
> *First time I got it out, he thought I was gonna let him watch YouTube. But no, no, this is something different.* [Participant 9, interview 1]
>
> *It's a tool, isn't it? You're using it as a tool just the same you would as a as a piece of paper.* [Participant 4, interview 2]

Theme 3.2: Using a Phone Is Inappropriate

Some parents were worried about using a phone as part of parenting. Only 1 parent strongly believed it was wrong, suggesting that a phone could form a barrier. Other parents expressed qualified concerns, which were overall outweighed.

> *I also don't think it's good practise to be using your phone when you're trying to sort that. If my children need attention and they're needing intermediate intervention there and then, it's not good for me to be having my phone in my hand.* [Participant 2, interview 2]
>
> *Some people don't like to see phones and stuff right before bed, but it doesn't seem to really affect her.* [Participant 5, interview 2]
>
> *I have issues as a professional with electronics and devices and as a parent and I can limit it, but in this case I don't see it as a problem.* [Participant 4, interview 2]

Theme 3.3: Phones Are Helpful and Convenient

Parents who compared the phone with other parenting resources could also identify advantages to using phones. The responsiveness and graphic interface of smartphones were seen as advantages. The possibility of a prompt card they could take anywhere was also seen as a strength. The use of the phone also created a warning sign, giving children a chance to de-escalate.

> *There's only so many visual aids I can have, you know? I mean, I know I printed out something that was like quite a nice little caption type stuff with the plan to laminate it, to put it in his room. But I'm like…actually in the heat of the moment…he doesn't tend to go to sit in his room in his day.* [Participant 11, interview 2]
>
> *It's not a distraction. it's a useful tool to have, especially when you're thinking "what should I do?" or "how should I do it?"* [Participant 1, interview 2]
>
> *I think even (child), when he's watching me, he knows the phone comes out, he knows what's coming next as well.* [Participant 4, interview 2]

Illustrative Case Vignettes

The case vignettes illustrated the way parents talked about their family life and the challenges they faced as well as capturing the personality of the parents and the way the relationships within their families impacted the response to the app. The vignettes draw attention to how siblings who display less prominent behavioral problems were sometimes able to use the app to regulate their emotions. The humor and closeness within families are highlighted by the way parents and children respond to the app. Textboxes 1 and 2 give illustrative examples of the case vignettes, and Multimedia Appendix 2 gives all 10 case vignettes.

Textbox 1. Illustrative case vignette 1 (participant H).

Before she had her twins - both 3 years old now - H used to work at a parenting assessment centre. She also has a 6 year old who can become violent and sometimes hits her. She finds it hard to know how to react. She's completed Triple P in the past and he is awaiting a neurodevelopmental assessment. H was interested in trying out the app to give her new ideas and resources for managing this violence. She sometimes used time outs, but she found it difficult because their house is quite open plan so there's not much privacy. More likely, her 6 year old announces his own time out and takes himself off to his bedroom.

She read through the information pages when she got the app and tried to start using more praise. She was surprised to see that she didn't have to insist her children apologised when they were done and found that this change made life easier. She mentioned she had re-read the information pages before we met. In fact, she had memorised so much of the information on the app that she did not use the timer; instead she used the kitchen Alexa and the Google Home in the lounge to set the timers. The main problem with the app is that she doesn't always have her phone on her; then again sometimes the smart speakers do not recognise her voice so no technology is perfect.

Textbox 2. Illustrative case vignette 2 (participant V).

Sometimes when your child is really winding you up and upsetting her siblings, V explains, it is hard to manage your own emotions. When everybody has fallen out, you know what they really need is a hug to make everything ok again, but you don't really feel like hugging them. It's good to have the app as a reminder to do that.

V has four children. It's not that they're naughty children but they do get really upset if she buys the wrong things from the shop. She tries to take their PS5 off them when they are badly behaved. She doesn't smack her children but she thinks some people probably do and reckons that the app creates an alternative model for their relationship, even suggesting that ending with a hug will have positive oxytocin effects on family life.

She used the app 2 - 3 times each week, including half term, but didn't need it the week before we spoke. Her son got the hang of taking 30 seconds of calming down, but her daughter was a little confused about what she was supposed to do. By the end of the three weeks her son knew what was going to happen when she took her phone out and could anticipate calming time.

Discussion

Summary of Results

This study aimed to evaluate the subjective experience of parents using a digital microintervention to support evidence-based parenting skills. In total, 11 parents of 33 children were interviewed before and after using a mobile app hosting 3 digital microinterventions, and thematic analysis was performed. Many parents used the app in ways they found convenient rather than strictly following the instructions they were given. Several parents experienced barriers to using the app including not having the phone to hand, forgetting about the app, the situation being too urgent, or not finding they were getting good results. Parents and children responded differently to the use of the phone; some were surprised, others explained nuanced concerns, and others wholeheartedly embraced the convenience of mobile technology. Future digital microintervention developers should keep in mind that parents are likely to use the app pragmatically rather than following instructions, may struggle to use a complex app under pressure, and are likely to hold complex feelings about parenting with an app.

Comparison With the Literature

The main problems parents noticed related to user interface problems including occasional freezing and navigation problems. Similar problems have been described in depth by MacKinnon et al [33], who described many practical challenges that arise in the implementation of an app for parents. As in their study, the app contained bugs due to the rapid build of the app under cost pressure. However, we suggest it is more efficient to run early tests of rapidly developed apps, which may contain bugs, in order to evaluate whether the underlying theory of behavior change works well rather than build a perfect app before testing it, in keeping with the principle of continuous innovation [34].

Many parents used the app in ways that were unexpected by researchers and out of keeping with the instructions they were given. Our intervention differed from common modes of parenting skills training, such as facilitator-led groups or e-learning videos, in that our intervention could be used in different ways [8,35]. We suggest digital microinterventions aiming to empower parents with digital tools are likely also to benefit from a group facilitator.

Parents held diverse views over whether using their phones to support their child’s behavioral and emotional well-being was appropriate, both in terms of whether they supported or opposed it and how far their views were nuanced or rigid. Previous research has revealed wide heterogeneity of attitudes throughout digital parenting, but there is little previous research on attitudes to using parenting apps, partly because the rapid pace of technological change precludes the formation of social norms [36]. Given the complex interaction of difficult family circumstances and shifting social norms, it is perhaps unsurprising that attitudes to technology have been uncorrelated with parenting app uptake [37]. The case vignettes illustrated how included parents had explored many other solutions in the past but maintained hope that the next solution would improve family life, and this is valuable in itself, in that when parents are more hopeful, there is greater parental well-being, child adjustment, and family resilience [38].

Strengths and Limitations

This study provides novel insights into how parents use an app with in-the-moment advice for supporting children through behavioral and emotional challenges. The use of qualitative analysis captured the diversity of views and uncovered some unexpected results. The use of illustrative case summaries illustrated how the app fitted into the wider context of family life, a feature often missing from pilot studies. However, app use was all self-reported, and no objective analytics were used, and as such, there is a risk that social desirability bias could lead to upwardly biased reports. Moreover, the way parents used the app in unexpected ways would have confounded objective analytics. The sample size was appropriate to evaluate the way parents used the app and to inform future development, but it was too small to draw conclusions about the proportions of parents who used the app in different ways or to make inferences about changes in child behavior [22,23]. This study used a self-selecting sample who may be more open to parenting apps than the general population of parents seeking parenting support, potentially leading to greater reported enthusiasm for the app than would be found with a general population sample. In addition, we were unable to recruit any fathers into this study, limiting the generalizability of this study to mothers.

Implications for Future Research

This study has implications for people developing apps to support parenting skills. Scholars should expect some resistance from parents who are wary of digital interventions but should also anticipate that other parents will nevertheless be open to using an app. Apps should facilitate several different levels of engagement (perhaps covering information, reflection, and in-the-moment guidance) that would allow parents with some qualms to begin to benefit from the app. This way, the largest number of parents can be supported by digital parenting interventions in a way they feel comfortable with. Alternatively, insights from behavioral science such as reminder notifications and incentives may be incorporated to prompt people to use parenting apps in keeping with suggestions, as has been attempted elsewhere in mental health care [39].

For a range of reasons, some parents occasionally found it impractical to use the phone in the heat of the moment. Some parents found a workaround in the use of home speakers. We suggest that future digital parenting skills programs incorporate home speakers. Although individual parenting skills have been built into home speaker apps in the past, families would benefit more from support integrating home speakers, smartwatches, and tablets with mobile apps [16].

Similarly, parenting apps should be designed to make it easy for parents to achieve their own personal goals, otherwise, parents will use the app in unintended ways that suit their family. Incorporating more personalization into parenting apps can support parents to use generic digital tools in ways that target the particular challenges affecting their families. Apps should provide evidence-based advice alongside useful tools.

Future studies should explore whether the finding that parents use digital microinterventions differently than guided is replicated among other groups of parents.

Conclusions

This study has described how a sample of mothers used an app designed to support evidence-based parenting skills following previous attendance at a parenting program. Digital parenting support is a rapidly growing area, and it is important that a wide range of possible interventions are offered to parents so they can find an approach that suits the needs of their families. Rapid pilots, such as this study, offer a comparatively cheap way of evaluating whether an app is suitable for parents and provide an opportunity to screen for areas to improve the intervention. In the future, we recommend researchers ensure parents' preferred approaches match up with the directions they are nudged toward by digital interventions.

Conflicts of Interest

NH and PW are named in a division of proceeds agreement for a parenting app owned by University of Warwick. The other authors declare no conflicts of interest.

Abstract

Background: A smartphone app, Parent Positive, was developed to help parents manage their children's conduct and emotional problems during the COVID-19 pandemic. A randomized controlled trial, Supporting Parents and Kids Through Lockdown Experiences (SPARKLE), found Parent Positive to be effective in reducing children's emotional problems. However, app effectiveness may be influenced by a range of child, family, socioeconomic, and pandemic-related factors.

Objective: This study examined whether baseline factors related to the child, family, and socioeconomic status, as well as pandemic-related disruption circumstances, moderated Parent Positive's effects on child conduct and emotional problems at 1- and 2-month follow-up.

Methods: This study was a secondary exploratory analysis of SPARKLE data. The data set included 646 children (4-10 years of age) with parents randomized to either Parent Positive (n=320) or follow-up as usual (n=326). Candidate baseline moderators included child age, gender, attention-deficit/hyperactivity disorder symptoms, parental psychological distress, family conflict, household income, employment status, household overcrowding, and pandemic-related disruption risk (ie, homeschooling, lockdown status, and isolation status). Child conduct and emotional problem outcomes measured at 1- (T2) and 2-months (T3) post randomization were analyzed using linear mixed-effects analysis of covariance models adjusting for baseline (T1) measure of outcome and including intervention and intervention by time point interaction terms allowing for different effects at the 2 time points. Moderation of intervention effects by baseline factors was assessed by replacing the intervention by time interaction terms with intervention by time point by baseline moderator interaction terms.

Results: Child gender was a significant moderator of the Parent Positive versus follow-up as usual effect on emotional problems (B=0.72, 95% CI 0.12-1.33; P=.02). Specifically, the effect of Parent Positive was close to significant (T2: B=–0.41, 95% CI –0.82 to 0.0004; P=.05) or significant (T3: B=–0.76, 95% CI –1.22 to –0.30; P<.001) in males only when compared with females, and males experienced a significantly larger reduction in emotional problems than females in the Parent Positive arm at the 2-month post randomization time point. None of the other investigated baseline factors moderated effects on emotional problems, and no factors moderated effects on conduct problems.

Conclusions: This study highlights Parent Positive’s potential for effectively reducing emotional problems in primary school-aged male children across a wide range of families. However, due to limited variability in the demographic background of the families, cautious interpretation is required, and replications are necessary in diverse samples with longer follow-up times.

KEYWORDS

parenting; intervention; smartphone app; randomized controlled trial; COVID-19 pandemic; moderators; conduct problems; emotional problems

Introduction

Background

Child conduct and emotional problems are a public health concern due to their negative impact on individuals, their families, and society [1]. Conduct problems are characterized by oppositional, disruptive, or aggressive behaviors [2], while emotional problems include anxiety and depression [3]. Conduct and emotional problems frequently co-occur [4] and can disrupt daily functioning, mental health, and social interactions [5]. If left untreated, these issues may elevate the likelihood of mental disorders, substance use, and delinquency in childhood and adolescence [6], as well as criminality in adulthood [7]. Children were particularly vulnerable to mental health difficulties during the global COVID-19 pandemic, likely due to COVID-19 mitigation strategies imposed on families by governments (eg, lockdowns, social isolation, and school closures) [8]. In a large cohort study conducted in the United Kingdom—COVID-19: Supporting Parents, Adolescents, and Children During Epidemics (Co-SPACE) [9]—lockdowns coincided with increased conduct and emotional problems in participating primary school-aged children.

Child conduct and emotional problems can be effectively reduced by behavioral parenting training that aims to enhance parenting practices [10]. However, financial costs, lack of access to transport, and stigma limit participation in these interventions, which are typically delivered face-to-face [11], and there were particular access issues during lockdowns. To increase accessibility, such interventions have shifted to smartphone app–based delivery formats [12,13]. Recently, Kostyrka-Allchorne et al [14] developed an evidence-based smartphone app, Parent Positive, that aimed to support parents and carers (henceforth referred to as parents) within the general population during the COVID-19 pandemic. Results from a randomized controlled trial (RCT)—Supporting Parents and Kids Through Lockdown Experiences (SPARKLE) evaluating the effects of Parent Positive versus a follow-up as usual arm (FAU)—showed that Parent Positive significantly reduced child emotional, but not conduct, problems [15] at 1- and 2-month follow-ups as compared with FAU.

While there were benefits of Parent Positive for the whole sample, as common for many interventions, there may be considerable variation in its benefits between individuals. In this case, it becomes important to identify factors influencing intervention outcomes to support a more targeted intervention approach. The literature describes such factors as intervention moderators, as they interact with the intervention and improve outcomes for some over others [16,17]. Exploring these moderators could improve understanding of which interventions are beneficial for whom, enabling clinicians to tailor recommendations to the most effective interventions [17,18]. We note that 1 moderation hypothesis was evaluated as part of the main SPARKLE trial analysis and was published in the main results paper: the effect of Parent Positive on conduct problems did not differ by levels of conduct problems at baseline [15].

The examination of moderator effects on child outcomes in previous studies of parenting interventions has been somewhat limited. Rather than conducting moderation analyses, some studies have primarily focused on assessing associations between various factors and outcomes only within groups exposed to interventions, or across the trial sample as a whole [16,19]. It is essential to distinguish this approach from moderation analyses, which involve investigating whether the effect of an intervention differs by the level of baseline characteristics or factors [16]. In this regard, there has been a somewhat limited number of studies explicitly exploring moderation effects in parenting interventions.

Most of the research on moderating factors in parenting interventions has examined how child, family, and socioeconomic factors influence the effectiveness of these interventions in addressing child conduct problems. Overall, the evidence regarding which moderators of parenting interventions are impactful on child conduct problems is somewhat mixed. The consensus from most meta-analyses suggests that child age [20-22] does not significantly moderate the effects of parenting interventions. Regarding child gender, while a meta-analysis found that boys benefitted more than girls from a parenting intervention [20], 2 RCT studies did not find any moderation effects related to child gender [23,24]. In the context of attention-deficit/hyperactivity disorder (ADHD) symptoms, multiple meta-analyses did not identify ADHD as a significant moderator of parenting intervention effects on child conduct problems [20,25,26].

Recent systematic reviews [19,27] exploring moderating effects of family risk factors, such as parental psychopathology, life stress, and family conflicts, reported no impact of these factors on effectiveness of parenting interventions for child conduct problems. Conversely, 1 meta-analysis indicated that children exhibited greater improvements when their mothers displayed elevated levels of depressive symptoms [26].

When examining socioeconomic status as a moderator in parenting intervention studies, the results have been less consistent. Most research indicates that these interventions maintain their effectiveness across different socioeconomic backgrounds [19,27], with recent meta-analyses and reviews [20,25] finding no significant moderation effects of socioeconomic characteristics on child conduct problems. However, other studies have suggested that socioeconomic disadvantage may lead to less positive child outcomes [21,28].

However, several of these moderator analyses faced limitations attributed to small sample sizes (ie, fewer than 70 participants in each arm of an RCT study [23]), likely lacking power to detect an effect that exists (type II error) [19]. In addition, there were variations in intervention components, including content, delivery format, length, and therapist contact [19]. These variations may have contributed to a lack of clear results, as what moderates intervention effects on outcomes likely varies across different interventions [19]. Furthermore, while previous research on parenting interventions has primarily examined moderation effects of child, family, and socioeconomic characteristics [19], recent pandemic-related disruptions could also influence intervention outcomes on children during the pandemic due to associated challenges. Consequently, the negative impact of mitigation policies [29] could influence how children and families respond to parenting interventions. For example, joint confinement and isolation from support networks, with parents often having to manage competing homeschooling and work demands have placed great pressure on parent-child relationships. In turn, it could have been more difficult for parents to engage within a self-directed universal intervention. This highlights the importance of examining moderating factors of a digital intervention within the context of the COVID-19 pandemic, even if previously studied and not found to be significant moderators, as the distinctive circumstances may yield diverse outcomes.

Objectives

This study aimed to test whether child, family, socioeconomic, and pandemic-related circumstances at baseline moderated Parent Positive effects on child conduct and emotional problems at 1- and 2-month follow-up in the SPARKLE trial. Given the inconsistent previous findings regarding moderators of parenting interventions and the novelty of the intervention [19], we chose an exploratory approach. The following factors, thought to be potential moderators, were used to construct a multivariate model: child age, gender, ADHD symptoms, parental psychological distress, family conflict, household income, employment status, household overcrowding, and pandemic-related disruption risk.

Methods

Study Design

This study was a secondary analysis using repeated-measures data from SPARKLE—a parallel, 2-arm, superiority RCT [14]. SPARKLE tested the effects of Parent Positive compared with FAU. Recruitment commenced in May 2021 during the COVID-19 pandemic and was a Trial within a Cohort [30] embedded in the general population Co-SPACE study [29]. The primary outcome variable was parent-reported levels of child conduct at 1- and 2-month post randomization, with emotional problems measured at the same time points as an important secondary outcome. Throughout the paper, we will refer to the "main analysis" or "main analysis models." By this, we mean the analysis we used to obtain the main trial results [15]. The main trial outcomes indicated that Parent Positive significantly reduced emotional problems but not conduct problems [15] when compared with FAU at both the 1- and 2-month follow-ups.

Ethical Considerations

Ethics approval was granted by King's College London (reference: HR–20/21-21451) and the University of Oxford (SPARKLE reference: R73153/RE001; Co-SPACE reference: R69060/RE001).

Written informed consent was originally provided by participants for the primary trial, covering the use of their data in secondary analyses without requiring additional consent. Participants were fully informed of their rights, including the ability to withdraw from the study at any time without consequence. Participant data were deidentified using unique study IDs, with raw data from the SPARKLE trial deposited in the UK Data Service repository [31]. A data privacy notice was made available on the study website. As compensation for their time, participants received 2 £5 (£1=US $1.26 at time of conversion) web-based shopping vouchers upon completing each follow-up questionnaire. Further information can be found in the SPARKLE protocol [14] and the main trial results article [15].

Participants

A total of 100% (646/646) children with parents were recruited into SPARKLE between May 19, 2021, and July 26, 2021. Parents were either part of the Co-SPACE cohort before the trial or were eligible to join Co-SPACE (aged 18 years and older, UK residence, informed consent) and SPARKLE after the start of the trial. In addition to the Co-SPACE criteria, SPARKLE participants were required to have a child aged 4-10 years and a smartphone to access Parent Positive (Android: operating system OS 8-9 or higher; Apple: iOS 12-13 or higher).

Procedures

Data Collection

Participants were invited to SPARKLE via a Qualtrics Co-SPACE survey between May 19, 2021, and July 26, 2021, and confirmed their eligibility before giving written e-consent. After completing baseline measures, participants were randomized to either Parent Positive or FAU and automatically informed about their allocated group through the Qualtrics Randomizer function. Participants (320/646, 49.5%) allocated to the Parent Positive arm received free access to Parent Positive from randomization until November 30, 2021. Data were collected at baseline (T1), 1-month (T2), and 2-months (T3) post randomization (via Qualtrics as part of Co-SPACE). Further details about the procedures, including the trial CONSORT (Consolidated Standards of Reporting Trials) diagram, can be found in the main trial results paper [15].

Interventions

Parent Positive

Parent Positive is an evidence-based self-directed smartphone app delivering support to parents with content organized in 3 zones. The first zone, Parenting Boosters, provided parenting advice on common challenges through 8 animations narrated by celebrity parents. The second zone, Parenting Exchange, provided access to a moderated support platform to connect with other parents and submit questions to experts in the field of child behavior and mental health. The third zone, Parenting Resources, provided parents with links to evidence-based parenting resources. No specific order or time was necessary for accessing the zones. Further details about the intervention can be found in the main trial results paper [15].

Follow-Up as Usual

Participants (326/646, 50.5%) randomized to FAU received no intervention during data collection. After their follow-up at T3, they received free access to Parent Positive until November 30, 2021.

Measures

Clinical Outcomes

This section describes the clinical outcomes assessed in the study, focusing on child conduct and emotional problems.

Child Conduct and Emotional Problems

The clinical outcomes were parent-reported levels of child conduct and emotional problems measured by the conduct and emotional subscales of the Strengths and Difficulties Questionnaire (SDQ) [32]. Each subscale consists of 5 items with response options ranging from 0 (Not true) to 2 (Certainly true). An overall subscale score was derived from summing the scores of individual items for each subscale, with higher scores indicating greater severity. The internal consistency of the SDQ is good (Cronbach α=0.73) [33].

Candidate Moderators

The key candidate baseline moderator variables were child age, gender, ADHD symptoms, parental psychological distress, family conflict, household income, employment status, household overcrowding, and pandemic-related disruption index. The following section provides a detailed description of these child, family, and socioeconomic characteristics.

Child Characteristics

Child Age and Gender

Child age and gender were provided by parents at baseline in a form asking about background demographics. When responding regarding the gender of their child, 3 parents chose the option “prefer not to say.” Given the limited number of participants in this category, mean imputation was conducted to include these participants. However, when we explored gender-specific moderation effects, data of only the more prevalent categories of males and females were used due to the limited number of participants in the “prefer not to say” category.

Child ADHD Symptoms

Child ADHD symptoms were measured by the 5-item hyperactivity-inattention subscale of the SDQ as described in the “Clinical Outcomes” section [32], with response options ranging from 0 (Not true) to 2 (Certainly true). An overall subscale score was derived from summing the scores of individual items, with higher scores indicating greater severity.

Family Characteristics

Parental Psychological Distress

Parental psychological distress was assessed using the 21-item Depression, Anxiety, and Stress Scale (DASS-21) [34]. The DASS-21 is a self-reported measure of depression, stress, and anxiety symptoms [35], consisting of 3 subscales (7 items each) and response options ranging from 0 (Never) to 3 (Almost always). The total score was multiplied by 2 to obtain a DASS-42 equivalent score [14], ranging from 0 to 126. Higher scores indicate higher severity. It has excellent internal consistency (Cronbach α=0.93) in community samples [36].

Family Conflict

The Family Conflict Scale was developed for the Co-SPACE study [29] to assess family conflict. It is a self-reported 3-item measure of arguments and disagreements between family members (parents, parents-children, and siblings). In the Co-SPACE study, family conflict was associated with mental health symptom trajectories during the pandemic [37]. Response options range from 0 (Not at all) to 3 (Completely) and the total score ranges from 0 to 9, with higher scores indicating greater family conflict. The internal consistency in the Co-SPACE sample was Cronbach α>0.54 [14], indicating moderate reliability.

Socioeconomic Characteristics

Household Income

Household income, collected at baseline, was recoded into 2 categories: less than £29,999 (US $38,600.66) per year and greater than £30,000 (US $38,603.78) per year. To create similar-sized groups, this cutoff was chosen due to less representation of families from lower-income backgrounds.

Employment Status

Due to limited numbers, participants’ employment status recorded at baseline was recoded into two categories: (1) not in paid employment, which encompassed parents who were at university, unable to work due to disability, homemakers or full-time parents, unemployed and actively seeking work, or retired, and (2) in paid employment—which included those who were self-employed, working part-time, or engaged in full-time employment.

Household Overcrowding

Three demographic variables, collected at baseline, were used to compute the household overcrowding index. The number of adults and children (excluding the parent and child in SPARKLE) was each assessed using a single-item measure, with response options ranging from 1 (None, I am the only adult in the household; None, the child I am answering about is the only child in the household) to 7 (6 or more). To calculate the household overcrowding index, the total number of people was divided by the number of rooms where the family resided. A higher overcrowding index reflects a greater degree of household overcrowding.

Pandemic-Related Disruption Characteristics

Pandemic-Related Disruption Index

Several variables pertaining to pandemic-related disruption circumstances at baseline were available for this analysis. Among them, 3 variables were selected due to their significant variation in responses and aggregated to calculate a pandemic-related disruption index. The selected variables were lockdown status (no=0; yes=1), isolation status (living life as normal=0; social distancing=1; self-isolating=1), and physical school attendance (yes=0; no=1). Scores ranged from 0 (low disruption) to 3 (high disruption), with higher scores indicating a greater disruption. For the purposes of analysis, the 2 highest scores (2 and 3) were collapsed into 1 category due to the small numbers in these 2 groups. While interpreting values of the pandemic-related disruption index, it is important to consider that the trial commenced during a period when COVID-19–associated lockdown measures had somewhat subsided. Thus, the pandemic-related disruption index exhibited lower values, indicative of a reduced degree of disruption compared with the initial phases of the pandemic.

Statistical Analysis

The analysis plan was registered prior to completion of the analysis [38]. Data analysis was done using Stata (version 17.0; StataCorp) [39].

Base Model

Linear mixed-effects models (LMM) similar to those applied in the main SPARKLE trial analysis were fitted to identify moderators at T2 and T3. The dependent variables were repeated 1-month and 2-month outcome measures (ie, child conduct and emotional problems in separate models), with a random intercept at the participant level to account for the repeated measures. Regardless of observed significance, all models included the main RCT analysis clinical outcome model covariates (the intervention arm, time, the intervention arm by time interaction allowing for different effects at the 2 outcome time points, and baseline outcome measure) and prespecified covariates (child age and gender), as fixed effects [15]. Baseline covariates that predicted missing outcome data, including household income and the overcrowding index for both clinical outcomes, were also incorporated in the analysis, as fixed effects, to be consistent with the main analysis and to make the missing at random assumption of the maximum likelihood estimation algorithm more plausible.

There were several differences between the main trial analysis and the current analysis. In contrast to the main trial analysis, which used household income and the number of adults in the household as separate covariates [15], we used only the overcrowding index. This was because the overcrowding index—which incorporates the number of adults as part of its calculation—was of interest in this study, so we used it rather than number of adults to avoid collinearity. Employment status at baseline predicted missing outcome data of emotional problems and was also incorporated as a fixed-effect covariate in models for emotional problems. In the main analysis, mean imputation [40] was applied to address missing baseline data (including “prefer not to say” responses) for child gender, family conflict, overcrowding index, and physical school attendance (used in the construction of the pandemic-related disruption index). In addition, categorical income was imputed using the mode.

Textbox 1 presents a list of steps and regression equations for the models used in the analysis of child conduct problems. A corresponding list for the analysis of child emotional problems, which includes employment status as a covariate, may be found in the Multimedia Appendix 1.

Textbox 1. A list of steps and regression equations in the analysis of child conduct problems.

1. Base model (linear mixed-effects models [LMM]):
    - The base model can be represented by the following equation:

      $$Y = \beta0 + \beta1\text{ Intervention arm} + \beta2\text{ Time} + \beta3\text{ (Intervention arm} \times \text{Time)} + \beta4\text{ Baseline child conduct problems} + \beta5\text{ Child age} + \beta6\text{ Child gender} + \beta7\text{ Household income} + \beta8\text{ Overcrowding index} + \varepsilon$$
2. Univariate LMM:
    - Fit LMM for each baseline moderator variable of interest as an independent variable in the base model background. Note that we do not know whether a variable is a moderator unless the interaction term in the second equation is significant, but we use that term for consistency. The regression equation example is as follows:

      $$Y = \beta0 + \beta1\text{ Intervention arm} + \beta2\text{ Time} + \beta3\text{ (Intervention arm} \times \text{Time)} + \beta4\text{ Baseline child conduct problems} + \beta5\text{ Child age} + \beta6\text{ Child gender} + \beta7\text{ Household income} + \beta8\text{ Overcrowding index} + \beta9\text{ Moderator} + \varepsilon$$
    - Fit LMM models for each baseline variable of interest as an independent moderator to the model background. The regression equation example is as follows:

      $$Y = \beta0 + \beta1\text{ Intervention arm} + \beta2\text{ Time} + \beta3\text{ (Intervention arm} \times \text{Time)} + \beta4\text{ Baseline child conduct problems} + \beta5\text{ Child age} + \beta6\text{ Child gender} + \beta7\text{ Household income} + \beta8\text{ Overcrowding index} + \beta9\text{ Moderator} + \beta10\text{ (Intervention arm} \times \text{Time} \times \text{Moderator)} + \varepsilon$$
3. Multivariate LMM:
    - Fit forward stepwise LMM with identified main effects from univariate models.
    - Add main effects and 3-way interaction terms in a stepwise manner. The regression equation example is as follows:

      $$Y = \beta0 + \beta1\text{ Intervention arm} + \beta2\text{ Time} + \beta3\text{ (Intervention arm} \times \text{Time)} + \beta4\text{ Baseline child conduct problems} + \beta5\text{ Child age} + \beta6\text{ Child gender} + \beta7\text{ Household income} + \beta8\text{ Overcrowding index} + \beta9\text{ Moderator } a + \beta10\text{ (Intervention arm} \times \text{Time} \times \text{Moderator } a) + \beta11\text{ Moderator } b + \beta12\text{ (Intervention arm} \times \text{Time} \times \text{Moderator } b) + \ldots + \varepsilon$$

Univariate Predictor Mixed-Effects Models

Initially, LMMs were fitted. Each baseline variable of interest, as listed in the objectives section, was included as an independent predictor in the base model described in the previous section. This step allowed for the assessment of the strength of association of each candidate factor individually, determined by likelihood ratio tests and the significance (*P* value) of each variable in turn. Given that the moderating effect of background and pandemic-related factors on intervention effects was the primary focus of this paper [15], the univariate models (ie, adding 1 potential moderator as an independent variable within the base model background) were fitted with intervention arm by time by potential moderator variable interaction terms. Any variable with either a main effect or a main effect and interaction term test *P* value of <.2 in the univariate model was taken forward into consideration in the multivariate models described in the following section. In the analysis of a 3-level categorical variable, pandemic-related disruption index, omnibus tests of significance for the interaction terms were conducted. This methodology involved using a specific test called "testparm" within the Stata software which executed a Wald test.

Multivariate Predictor Mixed-Effects Models

Following the univariate analyses, forward stepwise LMMs were fitted to build multivariate independent variable models (ie, might include more than 1 potential moderator as independent variables) in terms of the candidate moderators. Each of the identified main effects (*P*<.2) from the univariate model was manually added one at a time in a descending order with the strongest effect first, as assessed by the largest likelihood ratio test statistic. This enabled us to examine the influence of a range of possible factors simultaneously and assess the contribution of each factor. For each main effect added to the multivariate model, either due to indicating potential 3-way moderation in the univariate model (*P*<.2) or being included as a prespecified covariate, the corresponding 3-way interaction term was added to the model. If no 3-way interaction term was identified in the univariate model (*P*<.2), the factor was included only on its own as a main effect. Main effects and 3-way interaction terms were added in a stepwise manner until no further main effects and interactions terms were found to be statistically significant (*P*<.05). Robust standard errors were used in all final models to account for slight heteroscedasticity of residuals.

Results

Sample and Clinical Characteristics

The identical sample was used in this secondary analysis as in the main paper [15]—consisting of 646 parents with eligible children (mean age 7.45, SD 1.67 years; 51.1%, 330/646 male). Given that most variables used were previously described in the main paper, comprehensive information on sample characteristics at baseline is shown in Table S1 in Multimedia Appendix 1 and the 2 clinical outcomes (child conduct and emotional problems) at all time points are shown in Table S2 in Multimedia Appendix 1. Two baseline variables, namely, employment status and pandemic-related disruption index, were not previously reported and can be seen in Table 1. Both variables appear to be balanced across the trial arms. Most parents of children were in paid employment and reported some level of COVID-19 pandemic–related disruption.

Table 1. Previously unreported baseline variables for randomized arms and overall.

Baseline variable	FAU[a] arm (n=326)	Parent Positive arm (n=320)	Overall (N=646)
Employment status[b], n (%)			
In paid employment	251 (77.0)	256 (80.0)	507 (78.5)
Not in paid employment	75 (23.0)	64 (20.0)	139 (22.5)
Pandemic-related disruption index[c], n (%)			
0	50 (15.3)	53 (16.6)	103 (15.9)
1	164 (50.3)	163 (50.9)	327 (50.6)
2 and 3[d]	112 (34.4)	104 (32.5)	216 (33.5)

[a] FAU: follow-up as usual.

[b] Employment status was recoded into not in paid employment (at university, unable to work due to disability, homemaker or full-time parent, unemployed and seeking work, retired), and in paid employment (self-employed, part-time, full-time).

[c] Higher pandemic-related disruption index (a 3-level categorical variable) indicates more pandemic-related disruption.

[d] The 2 highest scores (2 and 3) in the pandemic-related disruption index were collapsed into 1 category.

Moderation of Parent Positive Versus FAU Results on Clinical Outcomes

All results from univariate LMM are shown in Table S3 in Multimedia Appendix 1. Child gender, age, and ADHD symptoms, parental psychological distress, family conflict, household income, employment status, household overcrowding index, and pandemic-related disruption index did not significantly moderate the effects of Parent Positive on child conduct problems at T2 and T3 (Table S3 in Multimedia Appendix 1).

For child emotional problems, when accounting for other variables in the multivariate model, gender was a significant moderator of the Parent Positive versus FAU intervention effect at T2 and T3 (Table 2). Specifically, the Parent Positive versus FAU lower emotional problems effects were close to or significant in males only (T2: *B*=–0.41, 95% CI –0.82 to 0.0004; T3: *B*=–0.76, 95% CI –1.22 to –0.30), with this effect being significantly different in males as compared with females at T3, who did not show a significant reduction in emotional problems in the Parent Positive group (*B*=0.12, 95% CI –0.30 to 0.54; see Figure 1 and Table S4 in Multimedia Appendix 1). This result was similar to the moderation effect of child gender found in the univariate model (Figure S1 in Multimedia Appendix 1). No other significant moderation effects on child emotional problems at 1 and 2 months of follow-up were found. Candidate moderators that showed only significant main but not interaction effects (ie, no moderation) from the multivariate LMM are further discussed in Multimedia Appendix 1.

Table 2. Multivariate linear mixed-effects models for child conduct and emotional problems.

Baseline variable	SDQ[a] Child conduct			SDQ Child emotion		
	B	2-Sided 95% CI	*P* value	*B*	2-Sided 95% CI	*P* value
Time[b]	0.01	–0.12 to 0.15	.82	0.52	–0.09 to 1.13	.10
Randomization arm[c]	–0.01	–0.24 to 0.22	.94	–0.57	–1.50 to 0.35	.23
Randomization arm ×[d] time	–0.17	–0.39 to 0.05	.13	–1.07	–2.03 to –0.11	.03
SDQ Child conduct	0.64	0.57 to 0.72	<.001	N/A[e]	N/A	N/A
SDQ Child emotion	N/A	N/A	N/A	0.72	0.67 to 0.78	<.001
Child age	–0.01	–0.07 to 0.05	.84	–0.01	–0.09 to 0.08	.90
Child gender[f]	–0.23	–0.43 to –0.03	.03	0.01	–0.37 to 0.38	.98
Child gender × time	N/A	N/A	N/A	–0.45	–0.85 to –0.06	.02
Child gender × randomization arm	N/A	N/A	N/A	0.16	–0.43 to 0.75	.60
Child gender × time × randomization arm	N/A	N/A	N/A	0.72	0.12 to 1.33	.02
Household income[g]	0.07	–0.18 to 0.32	.59	–0.30	–0.66 to 0.06	.10
Overcrowding index[h]	0.01	–0.26 to 0.29	.93	–0.03	–0.56 to 0.50	.90
Employment status[i]	N/A	N/A	N/A	0.07	–0.25 to 0.38	.68
Family conflict	0.18	0.11 to 0.26	<.001	N/A	N/A	N/A
SDQ Child ADHD[j] symptoms	0.09	0.05 to 0.13	<.001	0.09	0.04 to 0.14	<.001

[a] SDQ: Strengths and Difficulties Questionnaire.

[b] Reference category: time 2.

[c] Reference category: follow-up as usual arm.

[d] ×: Interaction effect.

[e] N/A: not applicable (indicates absence of the covariate for the given model).

[f] Child gender (1: male, 2: female) was treated as continuous due to mean imputation (mean 1.49) conducted for 3 participants.

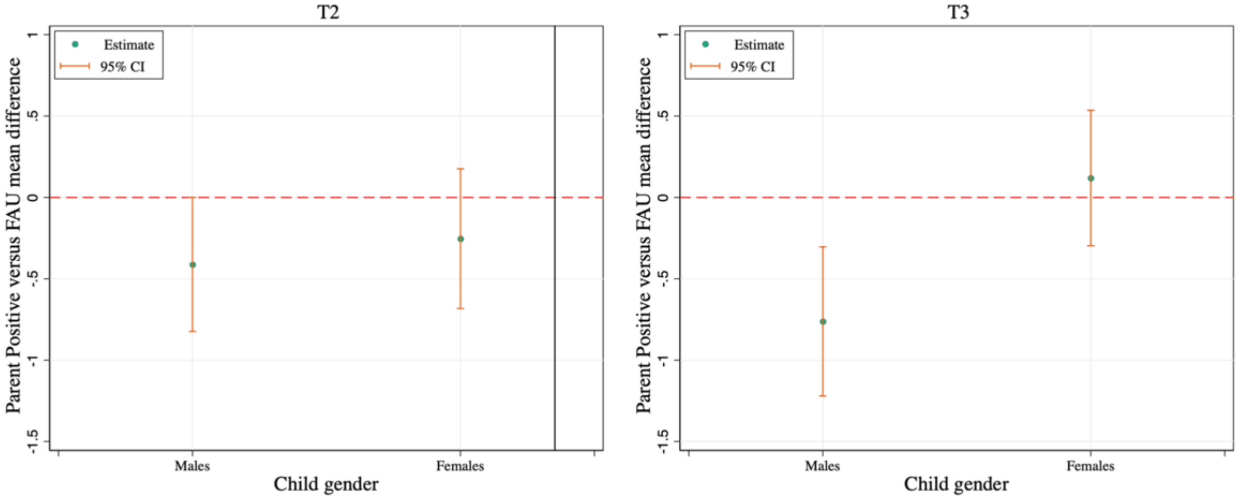
[g] Reference category: household income less than £29,999 (US $38,600.66) a year.

[h] Higher overcrowding index indicates more overcrowding at home.

[i] Reference category: not in paid employment.

[j] ADHD: attention-deficit/hyperactivity disorder.

Figure 1. Moderation of intervention effects on Strengths and Difficulties Questionnaire child emotional problems by child gender at time points 2 (1-month) and 3 (2 -months). Lower scores on the y-axis indicate a positive difference (ie, lower severity of child emotional problems). FAU: follow-up as usual.



Discussion

Principal Findings

Although research suggests that participant characteristics may impact the outcomes of parenting interventions, only a few studies have examined their moderating effects on child outcomes. Furthermore, the existing findings are often inconsistent and appear to depend on the specific intervention being studied [19,27]. As the Parent Positive app was developed to reverse children's increases in conduct and emotional problems experienced during the COVID-19 pandemic, moderating effects within this context have not yet been examined. This study aimed to identify child, family, socioeconomic, and pandemic-related disruption factors at baseline that may significantly moderate Parent Positive effects on children's conduct and emotional problems. The results showed that child gender was a significant moderator of the Parent Positive versus FAU effect on child emotional problems. None of the other investigated baseline factors played a moderating role in emotional problems, and no examined baseline factors were found to moderate effects on conduct problems.

This observed pattern of results in child conduct problems is similar to some previous research on face-to-face parenting interventions looking at child, family, and socioeconomic factors, indicating a lack of moderation effects [19,23,27]. However, it conflicts with some other studies suggesting significant moderation effects in the context of socioeconomic status [21], ADHD symptoms [41], and maternal depression [26]. Despite the growing emphasis on digital parenting interventions [12,13], the exploration of moderators in parenting interventions has predominantly centered on longer, face-to-face interventions guided by therapists [20]. This makes comparisons to most moderator studies challenging, considering the distinctive nature of Parent Positive as a short, smartphone app–based, and self-directed intervention, with an emphasis on fostering positive environments and experiences for both parents and children. Overall, these findings suggest that the Parent Positive effects on child conduct problems did not differ by the available participant characteristics. It should also be noted that a significant effect of Parent Positive versus FAU was not observed at 1- or 2-month follow-up on child conduct problems [15]. However, levels of conduct problems seemed to be decreasing at the 2-month follow-up after Parent Positive, possibly indicating that longer follow-ups may be necessary to see effects of the intervention on this particular outcome [42]. Subsequently, we might also see factors that moderate intervention effects.

After controlling for baseline emotional problems and other covariates, child gender was found to significantly moderate the effects of Parent Positive on child emotional problems at 1- and 2-month follow-up. While Parent Positive did not appear to be effective for females in terms of emotional problems, the intervention was effective for males. This reduction in emotional problem levels became more evident at the 2-month follow-up assessment. A similar effect was also found when examining moderation by child gender in the univariate model, enhancing reliability and robustness of this finding.

The finding of a moderation effect by child gender is similar to the finding of meta-analysis that looked at moderation of parenting interventions on child disruptive behaviors [20] but differs from findings in 2 RCTs [23,24]. This could be due to earlier studies predominantly involving males [43], whereas our sample had a more balanced representation of parents with male and female children. However, these prior studies examined the conduct problem outcome only, which might limit the comparability of the moderation effect on child emotional problems observed in our study. Notably, the emotional subscale of the SDQ used in this study encompasses dimensions such as anxiety and strongly aligns with anxiety measures across childhood [44], possibly allowing for meaningful comparisons with anxiety-focused treatments (eg, cognitive behavioral therapy). However, most studies in this domain have indicated that child gender does not moderate outcomes of treatments focusing on anxiety in children [45].

There are several other explanations. Parent Positive aimed to reduce child worry and enhance mood through positive parenting strategies while reducing harsh practices, aligning with evidence of parent training's impact on child internalizing problems [46]. Notably, parents frequently accessed booster components of Parent Positive that focused on family-related processes, potentially improving the overall emotional atmosphere in families using Parent Positive [15]. The observed gender moderation may be explained by these boosters having a more significant impact on males. Existing research shows that parents are more likely to use positive parenting strategies for females [47,48] while harsh parenting practices for males [49]. Consequently, it is possible that male children, who may exhibit more externalizing emotions such as anger [50], might have responded more robustly than females to the positive changes in parenting introduced by the boosters. The potential for a greater shift in parenting practices toward males may have contributed to the enhanced effectiveness of Parent Positive for male children in addressing emotional problems.

However, the lack of a more consistent gender effect across previous studies prompts considering additional factors that might contribute to this variability. Variations in study methodologies, sample characteristics, and cultural contexts across different studies could account for the inconsistent findings [19]. In addition, while changes in parenting practices may influence emotional outcomes in male children, the relationship with conduct problems in males might be more complex and multifaceted. Exploring this variability in future research, along with the interplay between child gender, parenting changes, and conduct problems, could provide a more comprehensive understanding of the observed patterns.

Another possibility is that societal gender expectations of emotion expression may have influenced our findings. Brody's theory [51] proposes that females are more likely to display internalizing emotions (eg, anxiety, sadness) while males tend to externalize emotions (eg, anger), which may contribute to the development of conduct problems [50]. These gender differences in emotional expression were supported by a meta-analytic review encompassing facial, behavioral, and vocal emotion expressions in children [52]. Given that our outcomes were parent-reported, and males are less likely to display internalizing emotions, it is important to consider the potential bias introduced by parents in accurately identifying and reporting emotions in males. Social expectations may also lead parents to anticipate and encourage less emotional expression in males than in females [51], possibly resulting in underreporting of emotional problems for male children [53]. To enhance the robustness of these findings, future research should consider incorporating additional measures of child emotional problems [53] from a range of informants (eg, teachers) and various technologies (eg, wearables that track heart rate variability as an indicator of anxiety).

Strengths and Limitations

Participant and pandemic-related disruption factors were explored in this study as potential moderators of Parent Positive in a large general population sample within a cohort. Unlike previous research on moderators of parenting interventions, child outcomes of both conduct and emotional problems were examined, with the latter essential given the pandemic-related increase.

A few limitations should be noted. First, child outcomes were parent-reported. Despite their importance, bias may have occurred because parents were unblinded [54]. While blinding of participants was not possible due to the research design, results should be replicated using more objective approaches such as observational measures of child behavior conducted by a blinded researcher [55]. Second, the relatively short follow-up times, chosen for practical reasons, could potentially mask the emergence of moderation effects that may require a longer duration to manifest. In addition, the low sociodemographic variability may have decreased statistical power and diminished chances to detect moderation effects by sociodemographic characteristics. Furthermore, because of the lack of variability in some of the sociodemographic characteristics (eg, household income and employment status), moderation of effects was examined in a binary way, and it is important to acknowledge that reducing this range into 2 categories may pose a limitation, as the distinct experiences within each category might vary considerably. Overall, replications with longer follow-up times are necessary, including with more families from low socioeconomic backgrounds, and racially and ethnically minoritized families to improve generalizability.

Finally, SPARKLE used a Trial within a Cohort design and participants were recruited from the Co-SPACE cohort, which allowed for rapid recruitment but had some limitations, as it likely attracted families with interest and internet access [56]. The sample also had higher levels of child conduct and emotional problems and ADHD symptoms than both the UK national survey [55] and the wider Co-SPACE study sample [29]. While levels of parental psychological distress were also higher than expected in the general population [36], they did not differ from levels reported in the wider Co-SPACE sample [37]. In addition, not all relevant moderators of interest from prior research were included (eg, young parent age and initial parenting confidence), as we relied on the available variables within the Co-SPACE data set. Future research incorporating a wider array of moderators in future studies could provide a more comprehensive understanding of intervention outcomes.

Conclusions

This study has demonstrated that Parent Positive has the potential to improve primary school-aged male children's emotional problems in a wide range of families. The findings suggest that the effects of Parent Positive on emotional problems do not differ for children with different levels of ADHD symptoms, socioeconomic status and household crowding, family conflict, and parental psychological distress. Pandemic-related disruption was also not found to influence the effectiveness of the app on child emotional problems. There were no differential effects of Parent Positive on conduct problems by any of the participant characteristics and pandemic-related disruption circumstances, noting that overall, the app was not found to be effective in addressing child conduct problems in the main SPARKLE trial analysis [15]. While our findings suggest positive emotional outcomes for male children, the exploratory nature of this study, along with potential limitations in statistical power to detect moderated effects and limited variability in some potential moderating variables, warrants caution in drawing definitive conclusions. However, if the male sex advantage in effectiveness turns out to be replicated, the reasons for this need to be identified and steps taken to adapt Parent Positive to increase its value for females. This could involve explorations of differences in the way that parents think about and react to emotional problems in their male and female children and subsequent change to the app to take account of these differences. Additional future research should focus on multivariate moderation analyses and replicate these findings in larger and diverse samples, with longer follow-up times, and across different contexts and settings, to better understand the app's effectiveness. In sum, while this study underscores the promising role of Parent Positive in fostering emotional well-being among male children, these findings are preliminary and continued research endeavors are essential to optimize its effectiveness and applicability in practice, especially in diverse familial contexts.

Conflicts of Interest

CC receives royalties from the sale of books for parents and clinicians on managing child anxiety problems from LittleBrown and Guilford Press. CD is the lead developer and has a nonfinancial interest in a number of parenting programs including Empowering Parents Empowering Communities, Helping Families Programme, Family Partnership Model, and BabyCHAT. EJSSB was involved in the development of the New Forest Parent Programme, Families Under Pressure and Parent Positive.

Receiving royalties for a book on the former. PW receives royalties from the sale of books for parents on helping their children overcome common psychological and emotional problems from LittleBrown. All other authors declare no conflicts of interest.

Abstract

Background: The 42 days after delivery ("fourth trimester") are a high-risk period for birthing individuals and newborns, especially those who are racially and ethnically marginalized due to structural racism.

Objective: To fill a gap in the critical "fourth trimester," we developed 2 ruled-based chatbots—one for birthing individuals and one for newborn caregivers—that provided trusted information about postbirth warning signs and newborn care and connected patients with health care providers.

Methods: A total of 4370 individuals received the newborn chatbot outreach between September 1, 2022, and December 31, 2023, and 3497 individuals received the postpartum chatbot outreach between November 16, 2022, and December 31, 2023. We conducted surveys and interviews in English and Spanish to understand the acceptability and usability of the chatbot and identify areas for improvement. We sampled from hospital discharge lists that distributed the chatbot, stratified by prenatal care location, age, type of insurance, and racial and ethnic group. We analyzed quantitative results using descriptive analyses in SPSS (IBM Corp) and qualitative results using deductive coding in Dedoose (SocioCultural Research Consultants).

Results: Overall, 2748 (63%) individuals opened the newborn chatbot messaging, and 2244 (64%) individuals opened the postpartum chatbot messaging. A total of 100 patients engaged with the chatbot and provided survey feedback; of those, 40% (n=40) identified as Black, 27% (n=27) identified as Hispanic/Latina, and 18% (n=18) completed the survey in Spanish. Payer distribution was 55% (n=55) for individuals with public insurance, 39% (n=39) for those with commercial insurance, and 2% (n=2) for uninsured individuals. The majority of surveyed participants indicated that chatbot messaging was timely and easy to use (n=80, 80%) and found the reminders to schedule the newborn visit (n=59, 59%) and postpartum visit (n=66, 66%) useful. Across 23 interviews (n=14, 61% Black; n=4, 17% Hispanic/Latina; n=2, 9% in Spanish; n=11, 48% public insurance), 78% (n=18) of interviewees engaged with the chatbot. Interviewees provided positive feedback on usability and content and recommendations for improving the outreach messages.

Conclusions: Chatbots are a promising strategy to reach birthing individuals and newborn caregivers with information about postpartum recovery and newborn care, but intentional outreach and engagement strategies are needed to optimize interaction. Future work should measure the chatbot's impact on health outcomes and reduce disparities.

Introduction

Maternal mortality rates in the United States are increasing; in 2018, the maternal mortality rate was 17.4 per 100,000 live births, nearly doubling by 2021 to 32.9 per 100,000 live births [1]. Furthermore, there are stark inequities for Black women, who in 2021 suffered 69.9 deaths per 100,000 live births compared to 26.6 for non-Hispanic White and 28 for Hispanic women [1]. While about half of all deliveries in Washington, DC are among non-Hispanic Black women, data from 2014 to 2018 indicate that 92% of all maternal deaths occurred among non-Hispanic Black women [2]. Infant deaths in the United States are also unacceptably high, at a rate of 5.4 deaths per 1000 births, but even higher in Washington, DC, at 6.8 per 1000 births [3,4]. Non-Hispanic Black women and infants bear the primary burden of these mortality inequities. Racially and ethnically minoritized individuals experiencing the highest risk of maternal and infant mortality may have lower access to care due to structural discrimination [5,6].

In the "fourth trimester" (first 42 days after birth), there are significant caregiving demands, physical recovery from childbirth, and emotional challenges [7]. Despite the high-risk nature of this period, birthing individuals in the United States experience little support for postpartum health, and some have challenges accessing a visit 6 weeks after delivery [7]. Missing postpartum care has devastating health consequences: 65% of pregnancy-related deaths occur in the first year after delivery, 35% of which occur in the first 42 days after delivery [8]. An estimated 60% to 84% of pregnancy-related deaths are preventable [8,9], and insufficient knowledge regarding warning signs of complications is identified as the most common factor contributing to pregnancy-related death [9]. In relation to infant mortality, 64% of infant deaths occur in the first 27 days, and about 14% of infant deaths are attributed to sudden infant death syndrome and unintentional injuries [3], some of which could be prevented with education [10]. Increased awareness of postnatal warning signs through universal education may empower birthing individuals to call their health care provider and to know when to seek immediate care [11,12]. For newborns, prompt follow-up care with a pediatrician and understanding warning signs to seek care may also decrease adverse events [13].

Digital technologies may help provide timely and trusted health information to patient populations [14] including birthing individuals [15]. Digital technology is often promised as an opportunity to reduce some educational burden on providers and increase patient knowledge [16]. Chatbots are one type of digital tool for delivering health information on a variety of topics, which allow for patient interactivity through mimicked conversation [16,17]. Chatbots are defined as any software programs simulating human conversation, which vary from rule-based, decision tree-style menus of options to advanced technologies relying on artificial intelligence (AI) [18,19]. Overall, chatbots have demonstrated a high acceptability rate among birthing individuals and newborn caregivers [20-22] and are effective at delivering interventions targeting birthing individuals' depression [23] and anxiety [24], as well as helping parents identify newborn developmental delays [25]. While these studies provide promise for health information delivery via chatbot, there is a need to further understand how chatbot outreach is received in real-world settings, particularly among historically marginalized birthing individuals.

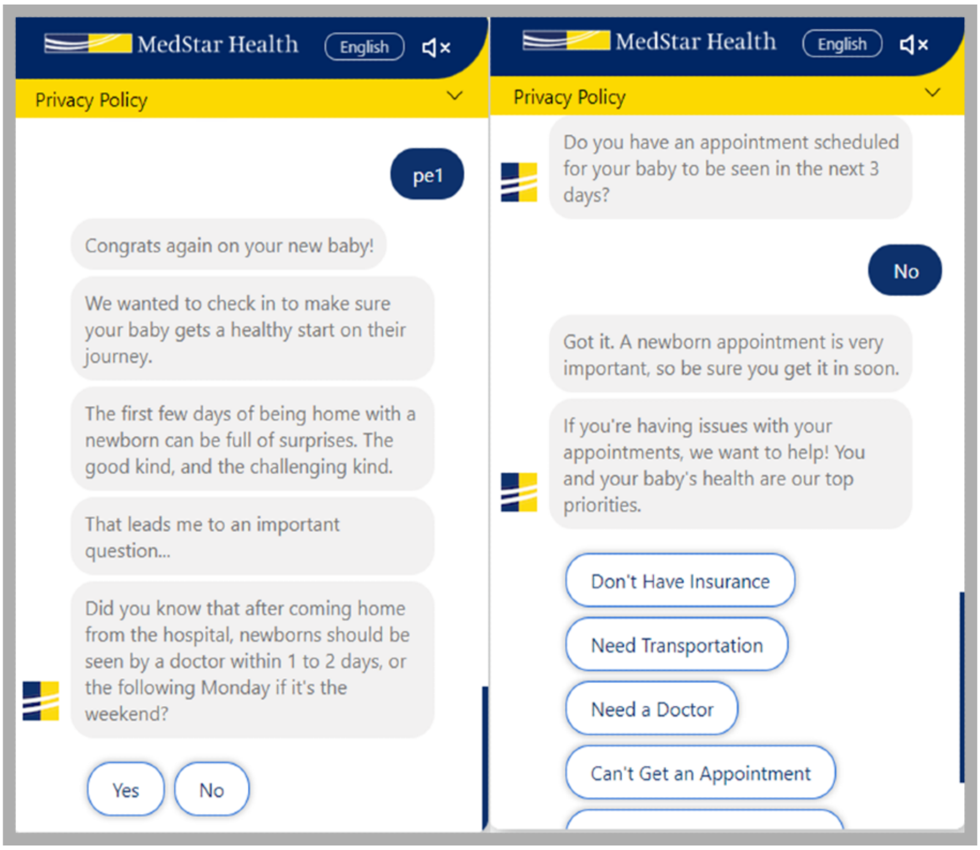
The goal of this study is to describe the development and refinement of chatbot outreach and content for postpartum individuals and newborn caregivers delivered as part of the standard of care. Postimplementation, we surveyed and interviewed socioeconomically, racially, and ethnically diverse patients who received chatbot messaging to improve the chatbot outreach and content.

Methods

Chatbot Development

We followed a person-centered approach to develop and refine a chatbot for postpartum individuals and newborn caregivers, with an emphasis on incorporating the perspectives and unique needs of our socioeconomically and racially diverse patient population [26]. The chatbot content was developed by a multidisciplinary team of experts in obstetrics, pediatrics, social work, psychiatry, mobile health, and health equity. The chatbot is intended to promote connection to care teams, provide education about warning signs, and deliver other postpartum and newborn information and resources (Figures 1 and 2). Two separate messaging streams (postpartum and newborn) were created because (1) newborns and postpartum patients are not always discharged together, and (2) some individuals may only need postpartum or just newborn content (eg, if there is a stillbirth, adoption, etc). We obtained a HIPAA (Health Insurance Portability and Accountability Act) waiver to use electronic health record (EHR) data to examine whether there was equitable chatbot engagement (defined as opening the chatbot link from the outreach message) by various patient characteristics.

Figure 1. Newborn chatbot examples.



pe1

Congrats again on your new baby!

We wanted to check in to make sure your baby gets a healthy start on their journey.

The first few days of being home with a newborn can be full of surprises. The good kind, and the challenging kind.

That leads me to an important question...

Did you know that after coming home from the hospital, newborns should be seen by a doctor within 1 to 2 days, or the following Monday if it's the weekend?

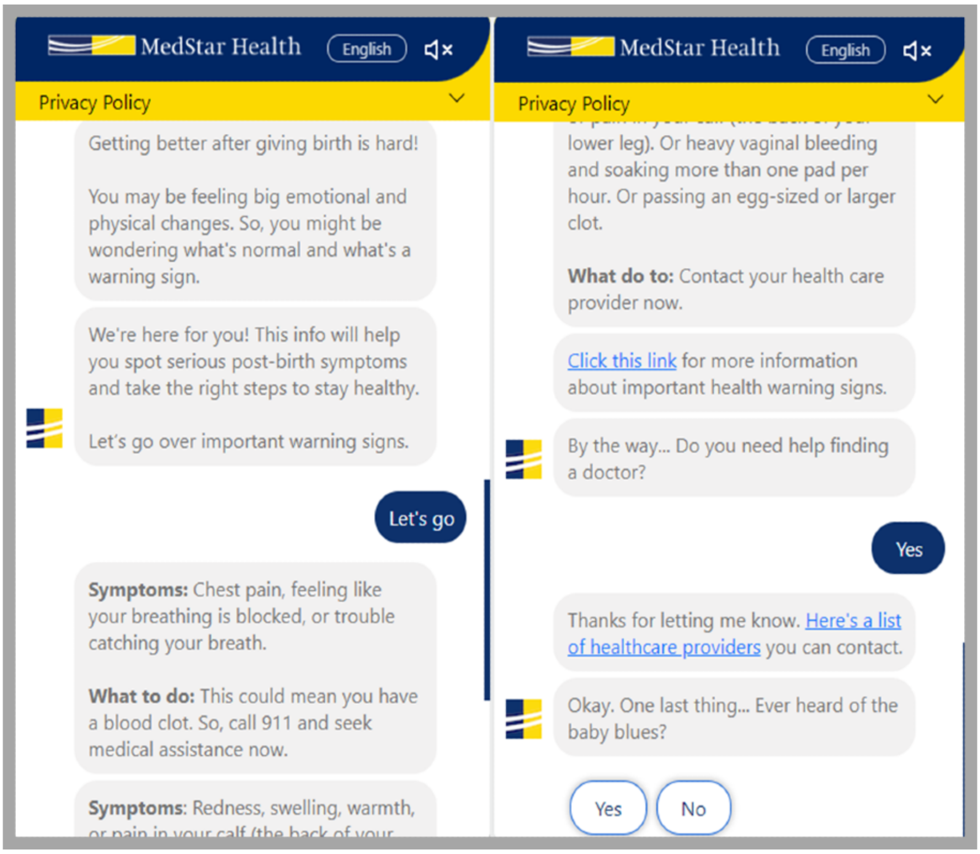
Do you have an appointment scheduled for your baby to be seen in the next 3 days?

No

Got it. A newborn appointment is very important, so be sure you get it in soon.

If you're having issues with your appointments, we want to help! You and your baby's health are our top priorities.

Figure 2. Postpartum chatbot examples.



Getting better after giving birth is hard!

You may be feeling big emotional and physical changes. So, you might be wondering what's normal and what's a warning sign.

We're here for you! This info will help you spot serious post-birth symptoms and take the right steps to stay healthy.

Let's go over important warning signs.

Let's go

Symptoms: Chest pain, feeling like your breathing is blocked, or trouble catching your breath.

What to do: This could mean you have a blood clot. So, call 911 and seek medical assistance now.

Symptoms: Redness, swelling, warmth, or pain in your calf (the back of your

lower leg). Or heavy vaginal bleeding and soaking more than one pad per hour. Or passing an egg-sized or larger clot.

What do to: Contact your health care provider now.

Click this link for more information about important health warning signs.

By the way... Do you need help finding a doctor?

Yes

Thanks for letting me know. Here's a list of healthcare providers you can contact.

Okay. One last thing... Ever heard of the baby blues?

Survey and Interview Recruitment

We recruited English- and Spanish-speaking birthing individuals and newborn caregivers from a diverse, mid-Atlantic urban hospital. We generated a list of potential participants from the EHR, purposively selected by age, racial or ethnic group, insurance type, and prenatal care location. Individuals were contacted via email and phone to invite them to complete either (1) a brief web-based survey that was conducted via REDCap (Research Electronic Data Capture; Vanderbilt University) or (2) a semistructured interview that was conducted by phone or video call using Teams (Microsoft Corp).

For web-based surveys, we invited a distinct list of respondents balanced across those who did and did not engage with the chatbot. Of the 410 individuals contacted for the survey completion, 104 (25%) individuals completed the informed consent, and 100 (24%) individuals completed the survey between May 15, 2023, and August 8, 2023. For interviews, we invited individuals who opened the chatbot. Of the 110 individuals contacted, 28 (25%) individuals agreed to participate, and 23 (21%) individuals completed a semistructured interview between March 13, 2023, and June 1, 2023; the remainder missed the scheduled interview time and were not interested in rescheduling.

Ethical Considerations

The study protocol was approved by the institutional review board from MedStar Health Research Institute (IRB #5741). All participants provided informed consent, and data were anonymized for analysis. Individuals were compensated US $10 and US $50 for their participation in the survey and interview, respectively.

Demographic Data Collection

Demographic data related to the study was obtained by directly querying the integrated enterprise EHR system’s database to describe patients’ general chatbot engagement. We included race (Back or African American, White, other, or unknown), age, and insurance type (private or commercial, Medicare or Medicaid, other, uninsured, or unknown) of the birthing individual. For the survey and interviews, we collected self-reported sociodemographic characteristics of gender identity (woman, man, nonbinary, transgender, or other), race (American Indian or Alaska Native, Asian, Back or African American, Native Hawaiian or Other Pacific Island, White, or Other), and ethnicity (Hispanic vs non-Hispanic). For the survey, participants reported their age, sexual orientation, highest level of education completed, English literacy level, employment status, living arrangement, and type of health insurance. Age and insurance type were obtained from the medical records of interview participants. Participants of both the survey and interview also reported the number of times they gave birth, the number of children they cared for, prenatal and postpartum care locations, newborn care, and if they had support at home recovering from childbirth and with newborn care.

Survey Measures

Survey questions about the chatbot experience covered three domains: outreach strategies, usefulness of content, and usability. Outreach questions included, “How often did you open the links provided in the emails and SMS text messages?” and “Would you say the timing of the messages was: too frequent, just right, or not enough?” (response options: never, rarely, sometimes, often, or always). Regarding content, participants rated their level of agreement to a set of statements regarding the usefulness of the topics included in the chatbot experience (strongly disagree=1 to strongly agree=5). Regarding usability, participants rated their level of agreement with the statement “The chatbot was easy to use” (strongly disagree=1 to strongly agree=5) [27]. Participants also rated their level of agreement for the following statement “I would recommend the chatbot to other people” (strongly disagree=1 to strongly agree=5).

Interview Process

We approached the interviews from a pragmatic qualitative framework [28], which emphasizes discovering problems, information gaps, and real-world solutions to the problem. Thus, we developed a standardized semistructured interview guide with a focus on the pragmatic understanding of postpartum and newborn concerns, how to improve chatbot engagement, and increasing engagement with chatbot content (Table 1). The interview guide was tailored by engagement; for example, if a participant did not remember receiving the outreach messages, they were asked to describe factors that typically influenced whether they opened SMS text messages and emails from their health care provider. Prior to and during the interview, participants received and were shown screenshots of outreach emails and SMS text messages, the chatbot interface, and the lists of topics included in both chatbots.

Table 1. Interview guide sample questions.

Domains	Example questions
Health concerns	• What were your biggest health concerns for you or your baby after discharge from the hospital?
Chatbot outreach strategies	• Can you tell me your impressions of the SMS text messages and emails you received after your hospital discharge? • What did you think of the timing when the messages arrived?
Chatbot content	• What are your thoughts about the topics that we included in the birthing recovery or postpartum chatbot? • What are your thoughts about the topics that we included in the newborn chatbot? • What could we do to better support birthing individuals or caregivers in accessing these resources?
Chatbot usability	• What aspects of the chatbot were most helpful? • What aspects of the chatbot were least helpful? • How hard was it to use the chatbot?

Data Analysis

Audio recordings from the interviews were transcribed and reviewed for quality control using Otter.ai and coded using Dedoose (SocioCultural Research Consultants). Three research team members (JNRR, CS, and MS) met to create the initial codebook with operational definitions for each code. The three team members then coded two randomly selected interviews individually and finalized the codebook together. The team members then triple-coded 3 additional interviews to meet an interrater reliability of 80% with JNRR. The team members independently coded the remaining interviews, with regular meetings to discuss inconsistencies and coding questions. We selected representative quotes and demonstrated theme salience by summarizing whether the sentiment was reported across most, around half, or a limited number of participants. Given the small number of interviews and the research team's interest in the depth of response rather than the quantity of responses, we did not present statistics on the number of individuals reporting a specific theme. Descriptive statistics were used to describe the quantitative data using SPSS Statistics (version 29; IBM Corp).

Results

Chatbot Strategy

The initial postpartum chatbot outreach message was sent the day after the birthing individual was discharged home from the hospital, and the first newborn chatbot message was sent to the newborn caregiver listed in the medical record the day after their newborn was discharged from the hospital. The postpartum chatbot outreach SMS text messages and emails were sent in the morning and the newborn messages were sent in the afternoon. In Table S1 in Multimedia Appendix 1, there is a full description of the original chatbot content by day of the outreach message. The content was rule-based and allowed for interaction using fixed logic; it did not permit open-ended questions from the user or responses from a care team. Both chatbots were sent approximately weekly during the first 42 days of posthospital discharge.

Overall Chatbot Engagement

In regard to the postpartum chatbot, a total of 2244 (64%) birthing individuals opened the chatbot (Table 2) between November 16, 2022, and December 31, 2023. When evaluated by racial group, 62% (n=969) of the Black users, 78% (n=384) of the White users, and 62% (n=891) of those classified as Other opened the postpartum chatbot. In addition, the proportion of patients who opened that chatbot increased by age; for example, 55% (n=183) of birthing individuals 21 years old and younger opened the chatbot compared to 68% (n=429) of birthing individuals aged 37 and older. By insurance type, 69% (n=971) of birthing individuals with private or commercial insurance and 63% (n=631) with Medicaid or Medicare insurance opened the chatbot.

A total of 2748 (63%) caregivers opened the newborn chatbot between September 1, 2022, and December 31, 2023. By racial group, 61% (n=1256) of the Black caregivers, 81% (n=449) of the White caregivers, and 61% (n=593) of those classified as Other opened the newborn chatbot. In addition, 58% (n=246) of caregivers 21 years old and younger and 69% (n=516) of caregivers aged 37 and older opened the chatbot. By insurance type, 71% (n=1185) of caregivers with private or commercial insurance and 61% (n=799) with Medicaid or Medicare insurance opened the newborn chatbot.

Demographics for Survey and Interview Participants

Participants’ average age was 32 (SD 5.38) years old in the surveys, and 31 (SD 7.05) years old in the interviews (Table 3). A total of 40% (n=40) of survey participants and 61% (n=14) of interview participants identified as Black, and 27% (n=27) of survey participants and 17% (n=4) of interview participants identified as Hispanic. Over half of the Hispanic participants (18/27, 67% in the surveys and 2/4, 50%) in the interviews) identified Spanish as their preferred language. One-third of the participants in both the surveys and interviews indicated that this was their first time giving birth. About half of the participants in the survey (n=55, 55%) and interviews (n=11, 48%) had public insurance. Most of the survey and interview participants reported that they had a postpartum provider (n=78, 78% and n=22, 96%, respectively) and primary care provider (n=73, 73% and n=18, 78%, respectively) and that their newborns were receiving care outside of the integrated health care system (n=84, 84% and n=20, 87%, respectively).

Outreach Strategies: Satisfaction and Recommendations

Most survey participants (n=83, 83%) reported that they understood why they were receiving the outreach messages (Table 4). However, many interview participants reported being surprised when they received the messages, as they did not expect them (Table 5). Still, participants in the interviews found the outreach messages to be helpful. Participants recommended that the chatbot should be introduced both in prenatal care and by the recovery care team prior to discharge.

Interview participants reported that they opened the outreach messages because the messages came from the hospital where they delivered. Most participants in the survey (n=70, 70%) and interview preferred receiving messages via text because it was more personal, easier to notice, and involved fewer steps than email. However, during the interviews, it was noted that those who preferred emails did so because they could open the chatbot on their computer, which provided additional confirmation that the outreach messages were legitimate and not spam or scam.

More than half of the survey participants (n=56, 56%) indicated they opened the weekly chatbot link often or always. In the interviews, some participants reported that their decision to open each of the weekly chatbot experiences was based on the information or topic in the outreach message, as they only opened the chatbot experiences that were relevant to them. The interview participants also identified barriers to chatbot engagement including feeling overwhelmed with information, multiple household responsibilities, and confusing the chatbot with a survey.

Participants reported that the outreach messages were useful reminders of self-care and feeling supported by the hospital. Participants liked that the outreach messages were short, straightforward, and could be opened at any time, as opposed to a phone call which would be missed if they were not available. Participants also liked when the messages indicated what information would be covered in the chatbot experience. They recommended that the initial outreach should provide more information about why they are receiving the messages, and that all the messages should indicate what will be covered in each of the chatbot experiences. Furthermore, participants recommended making the messages more inviting, personal, and targeted. Some participants expressed that the chatbot's wording should be appropriate to a diverse literacy level; for example, a few participants noted that the term "postpartum" could be confused with postpartum depression, and one participant suggested changing the term "chatbot" to something more friendly like "check-in messages." One participant talked about a previous experience with stillbirth and suggested the postpartum chatbot would have been useful as she recovered.

Table 5. Example of participants' interview responses by themes.

Themes	Quotes
Outreach strategies and timing	• "At the beginning, when I received the first message, I wasn't sure what to do, if should read it or not, later I decided to read it and I found it to be good, because it was good information." [Hispanic/Latina, Other, 38 years, female, 2 children] • "In the past, I was a victim of identity theft. I'm very leery about getting messages from different places ... It was one time where I thought that it was a scam but when I saw it said [health care system], that was my indication that it was something real, something important, and informational." [Non-Hispanic, Black, 35 years, female, 6 children] • "So the text here is quick, easy, it's telling you to the point, we know you're busy, you got a lot going on ... And typically, that's what people need these days ... There's something about that quick." [Non-Hispanic, Black, 40 years, female, 2 children] • "It was really helpful to have both emails and text messages, just as a follow-up in case I miss one or the other. But I felt it was like perfect timing, because it checked up on me." [Non-Hispanic, White, 31 years, female, 1 child] • "So, I may have opted out a little early. Which I feel like even though I did opt out I wish there was like another option that you know, I can get back in it ... Because at one point in time, I wish I was receiving the messages again after I opted out." [Non-Hispanic, Black, 25 years, female, 1 child]
Knowledge and information-seeking	• "I just relied solely on my family, I didn't really have resources to reach out to anything ... I didn't really have health concerns for myself, but for my son, it was just more so how to care for a baby that just got out the NICU. I didn't really have ... much information on things like that. So it was kind of like I had to learn by myself. And figure things I don't know." [Non-Hispanic, Black, 25 years, female, 1 child] • "There's some weird things that happened with the babies. There's like, how do you care for their umbilical cord? Once that falls off ... what do you do with it? That was a question I definitely Googled. They have weird skin stuff. What is normal? What's concerning?" [Non-Hispanic, White, 30 years, female, 2 children]
Chatbot content	• "I learned how to take care of my son, I learned how to take care of myself, [I received them] just recently leaving the hospital, I learned a lot of stuff." [Hispanic/Latina, Other, 29 years, female, 3 children] • "I didn't know anything about postpartum until I had my baby. So, really understand because it's like postpartum depression, like what you're talking about." [Non-Hispanic, Black, 22 years, female, 2 children] • "The one thing I can say I really enjoyed receiving messages about were the developmental milestones, because I always wanted to know if my baby was on track, being as he was premature baby ... And as a first-time parent ... It can be really overwhelming ... So being as though [health care system] was giving you information like vaccines, and you know, what to expect with these vaccines and things like that. I feel like that was very helpful..." [Non-Hispanic, Black, 25 years, female, 1 child] • "I was glad that it was put together because usually that is the time that I go through the worst end of postpartum depression. But even though I didn't have the effects of postpartum depression, like I usually do, this time around, I was just glad that it was something I could read to give, I guess you could say, some sense of comfort or hope to get me through it." [Non-Hispanic, Black, 35 years, female, 6 children] • "I feel like breastfeeding was the one thing that I was shocked by how hard it was. So, getting more support and encouragement would have been nice ... Feel like it's not just newborn care. That's also postpartum. My body too." [Non-Hispanic, White, 30 years, female, 2 children]
Chatbot usability	• "I think moms are getting the most information from their phones, and kind of a digestible bite size thing when you can, like, occasionally glance at your phone for a few minutes is helpful." [Hispanic/Latina, Other, 23 years, female, 2 children] • "It was really easy. I don't have any real complaints about it. It was very simple to use, in my opinion." [Non-Hispanic, Black, 23 years, female, 2 children] • "I had the information through text and email, and just the resources were really helpful, and then just how quickly the chatbot worked. And just that it also felt like I was talking to a real person, it felt like a very sophisticated robot ... And I remember, like, sharing those resources with my husband, too. So it was nice, because it like also added a source of credibility." [Non-Hispanic, White, 31 years, female, 1 child] • "Overall, just very helpful. And I thought it was really amazing to see ... just considering the generation that we are in, tech is constantly evolving. And I feel like the world should start evolving more, especially medical wise, just with technology and adapting, certain people that are getting more into technology. So, I thought that was very refreshing. Like I said, it's a very nice experience. Honestly, took me by surprise, I'm like, 'Woah, hospitals are doing this now?' Like this is great. But yeah, I thought that was pretty cool, too." [Hispanic/Latina, Other, 19 years, female, 1 child]

Themes	Quotes
Chatbot suggestions	• "It comes in English and I have to put it in the translator, and it gets a bit more difficult." [Hispanic/Latina, Other, 29 years, female, 3 children] • "...If there's some sort of way you can write in a question ... And even if it's not something that the chatbot can respond to, it can say, we received your question and someone will reach out to you." [Non-Hispanic, White, 30 years, female, 1 child] • "So maybe an opportunity of like, send this to like your husband, or whoever, like they need support. I know I needed a lot of support in those first two weeks because you're not supposed to go up and down the stairs. Things like that and how they can be supportive to you and the baby." [Non-Hispanic, Black, 26 years, female, 1 child] • "It would be great if all information appeared in one site that I could refer back to later and also have a choice of selecting which topic I want to learn about at any given time rather than a pre-determined order." [Non-Hispanic, Asian, 37 years, female, 1 child—Survey] • "...There could be a 12-week one, just because that's when a lot of transitions and a lot of people are going back to work or things like that." [Non-Hispanic, White, 30 years, female, 2 children]

Most participants in the survey (n=80, 80%) and interview liked the timing and frequency of the outreach messages, although a few survey participants (n=10, 10%) indicated that the messages were too frequent. Participants in the interviews and survey also recommended extending messaging to at least 12 weeks to support longer-term recovery and life transitions such as going back to work. One participant reported that she felt that the chatbot messages ended abruptly and recommended including a final message indicating that the chatbot experience was complete. Of note, one interview participant who opted out from the chatbot indicated regretting it and recommended including a summary of all the topics that will be covered before someone can opt out.

Chatbot Content Usefulness and Recommendations

Most of the participants in the survey and interview found all topics included in the chatbots to be useful. Participants noted that the chatbot information complemented and reinforced the information provided by their providers and at discharge. Some of the participants spoke about how the content supported them through their journey in their recovery and caring for their newborn. Specifically, topics rated as useful by the greatest percentage of survey participants included appointment reminders (n=59, 59% for newborn appointments and n=66, 66% for postpartum appointments; full results in Table S2 in Multimedia Appendix 1), and nearly a quarter of participants (n=22, 22%) thought that the resources to schedule appointments were useful. Participants further highlighted the importance of receiving tailored information for postpartum recovery. One interviewee noted that the information was beneficial for sharing newborn recommendations with other caregivers.

For the newborn chatbot, 86% (n=86) of the participants found the warning sign information to be useful and 58% (n=58) of the participants found the parental leave information to be useful. For the postpartum chatbot, 88% (n=88) and 86% (n=86) of the participants found the warning signs and postpartum depression information to be useful, respectively (Multimedia Appendix 1). For both the newborn and postpartum chatbots, interview participants recommended more information about breastfeeding (eg, engorgement or mastitis, how to latch, access to a pump, resources for lactation consultants, and differences between breast milk vs formula) and parental leave. Most participants also recommended that the resources to schedule and attend medical appointments (eg, transportation, childcare, or insurance recommendations) should be offered to all participants regardless of whether they indicate a need. Participants also requested information on how to improve communication with providers and more resources for emotional and practical support.

For the postpartum chatbot, survey and interview participants recommended adding additional information about postpartum recovery including mental health warning signs and support, vaginal birth, pain management, pelvic floor issues, and monitoring blood pressure. For the newborn chatbot, participants noted that it was important to add additional information about what is normal versus concerning for a newborn (eg, number of wet diapers, bowel movement texture and color, baby acne, cradle cap, umbilical cord, and circumcision recovery). Some participants also recommended adding specific tips on newborn care, such as changing newborn diapers, newborn sleep recommendations (eg, number of recommended hours, wake windows, and establishing sleep routines), and activities to do with a newborn. Participants with specific needs recommended additional targeted information; for example, participants with a premature newborn recommended adding specific information about premature newborns (eg, expected weight gain and recommended room temperature), participants with twins recommended including practical recommendations on how to care for twins, and participants with older children suggested more information about how to care for a newborn with older siblings at home.

Perceived Ease of Use

The majority of survey (n=81, 81%; Table 4) and interview participants who engaged with the chatbot found the chatbot easy to use. During the interviews, participants described the chatbot as personable and practical. Participants also liked that they could use their smartphones to open the chatbot. Most of the participants in the survey (n=72, 72%) and interviews indicated that they would recommend the chatbot to other people. Participants in the survey and interviews provided different suggestions to improve the delivery of chatbot information, which included a video or voiceover option, an option for patients to provide immediate feedback after navigating each experience, an option to share the chatbot content with their partner or other caregiver, and an option to easily go back to information of interest. Several participants recommended adding the capability to interact with a provider via the chatbot to answer nonurgent questions. Finally, Spanish-speaking participants recommended having the chatbot available in Spanish.

Discussion

Principal Findings

We found that the chatbot is a promising strategy to deliver relevant and timely education and referral to resources for birthing and caregiving individuals. To our knowledge, this is the first report on perceptions of a postpartum or newborn chatbot delivered at scale as part of usual care upon hospital discharge.

Previous studies illustrated preliminary interest in chatbots as a modality to receive information about pregnancy and postpartum concerns. Researchers who developed an artificial intelligence-based, open-ended question-and-answer chatbot using a community-engaged approach with pregnant women and new mothers of color also conducted community demonstrations to solicit feedback. They queried participants on interest in using a chatbot to receive information and found that 109 participants were highly receptive [20]. Our findings further expanded on the previous study by evaluating outreach strategies on how to best reach and engage patients by email and SMS text message.

This study suggests that the chatbot provided useful and timely information during the postpartum period. This is particularly relevant, as in a study with Black new mothers, none of the participants were able to identify more than five of nine key postpartum warning signs [29]. While we were unable to conduct a pre-post knowledge test through the chatbot, interview participants reported limited knowledge of key topics prior to discharge and found the postpartum warning signs and mental health information to be useful. Similar outreach and chatbot strategies targeting postpartum mental health issues have improved birthing individuals' well-being [23,24,30]. One study targeting postpartum depression found that patients who engaged highly with an AI chatbot had lower symptoms of depression during the postpartum period compared to patients with low engagement [23]. Other studies found that engaging with an SMS text-messaging program can reduce postpartum anxiety [24], and web-based courses that provide information to birthing individuals can lower anxiety and result in fewer emergency visits compared to standard of care [30]. Nevertheless, additional research is needed to understand how chatbots can serve to fill knowledge gaps in postpartum health care and impact postpartum and newborn health outcomes.

Chatbots provide a potential opportunity to create a sense of support for new parents or birthing individuals, which is important since social support is identified as a protective factor for postpartum depression and anxiety [31]. Our finding that more than 10% of the participants in the surveys and interviews reported that they did not have support for themselves or taking care of their baby after hospital discharge suggests an avenue for at least informational support through consistent outreach. Content also included in-person and web-based support communities that might be able to fill some of the gaps in support after delivery.

This study also elucidated postpartum individuals' and newborn caregivers' health information needs about postpartum and newborn care after discharge from the hospital. In general, participants desired more information about breastfeeding, postpartum recovery, mental health, and newborn care among other content areas. Participants who were planning to go back to work wanted more information about parental leave. These findings are similar to a scoping review reporting that nurses prioritized safety and avoiding adverse events after discharge (eg, the prioritized topics in our chatbot) and patients prioritized self-care, pain management, infant care, and parenting (eg, the topics many participants wanted to hear more about) [32]. Thus, increasing engagement with the newborn and postpartum chatbots may require including more material desired by patients to also deliver information about warning signs.

Limitations and Future Directions

While this study had an adequate representation of individuals from historically ethnically or racially minoritized populations, the chatbot was delivered in English and data collection was completed in English and Spanish. Although we shared screenshots of the outreach messages, chatbots, and topics covered by the chatbots during the interviews, the survey and interview relied on participants' recall of their experiences with the chatbot, which may have gotten confused with other outreach strategies they received including messages related to apps from their prenatal providers such as Babyscripts. Similarly, study participants might have more positive experiences with the chatbot compared to those we did not survey or interview. We attempted to mitigate this by including both people who did and did not engage with the chatbot. Finally, though participants indicated that the information provided in the chatbot was useful, we did not evaluate the impact of the chatbot on participants' knowledge, access to care, and overall well-being. Future research to examine how chatbot engagement affects patient knowledge about warning signs, appointment attendance, and other patient health outcomes is needed.

Conclusions

The postpartum and newborn chatbots were identified as an acceptable and useful strategy to provide information and resources to birthing individuals and newborn caregivers about postpartum recovery and newborn care. Nevertheless, future work should measure the impact of chatbots on specific postpartum and newborn health outcomes including health disparities.

Acknowledgments

This project was funded by the A. James and Alice B. Clark Foundation. Katarina E AuBuchon was supported by grant T32CA 261787. We also want to acknowledge the support of the DC Safe Babies Safe Moms Team, Doriun Brown, Christine Laccay, Shrey Mathur, and Orbita during the development of these chatbots, and Andrea Lopez for supporting recruitment efforts.

The datasets generated during or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

JNRR wrote the results with input from HA. KEA wrote the first draft of the introduction and discussion, and MS wrote the first draft of the methods, all with significant input from JNRR and HA. JNRR, MS, and CS engaged in data collection, data curation, and analysis. HJB managed the population chatbot data and assisted in data selection. ADT conceptualized the study and was responsible for funding acquisition. JNRR and HA were responsible for study methodology, project administration, and supervision of the study team. CS, KGG, ADT, LP, JAR, HJB, and ADT contributed to the development of the chatbot and to reviewing and editing the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Improved bone health during adolescence can have lifelong implications, reducing the risk of bone fragility.

Objective: This study aims to evaluate the effectiveness of an e-book in increasing knowledge about and promoting healthy practices related to bone health among Malay adolescents in Kuala Lumpur, Malaysia.

Methods: A total of 72 adolescents (female: n=51, 71%; age: mean 15, SD 0.74 y) were recruited from selected secondary schools. The participants answered a pretest web-based questionnaire on sociodemographic data, knowledge about osteoporosis, and physical activity. A video call was conducted to assess dietary calcium intake. Participants were provided with a link to an e-book on bone health and instructed to read it within 2 weeks. Postintervention assessments included those for knowledge, physical activity, dietary calcium intake, and acceptance of the e-book.

Results: There was a significant increase in the median knowledge score, which was 40.6% (IQR 31.3%-46.9%) during the pretest and 71.9% (IQR 53.9%-81.3%) during the posttest ($P<.001$). However, no changes were observed in dietary calcium intake or physical activity levels. Most participants did not meet the recommended calcium requirements (61/62, 98%) and exhibited sedentary behavior (pretest: 51/62, 82%; posttest: 48/62, 77%). The e-book, however, was well accepted, with the majority reporting that they understood the contents (70/72, 97%), liked the graphics (71/72, 99%), and approved of the layout (60/72, 83%) and font size (66/72, 92%) used.

Conclusions: The developed e-book effectively increases knowledge levels related to bone health and is well accepted among participants. However, this educational material did not improve bone health practices. Additional strategies are necessary to bridge the gap between knowledge and behavior change.

Introduction

Throughout the human life span, bone modelling and remodelling are continuous and vital processes that shape bone architecture, crucially contributing to peak bone mass attainment [1]. Childhood and adolescence mark crucial periods for rapid bone growth and peak bone mass—the highest bone mineral density (BMD) attained in one’s lifetime [2]. Improving bone health during these phases yields long-term benefits, reducing the risk of bone fragility and fractures later in life [3]. Since BMD typically declines with age, achieving peak bone mass by 30 years of age and maintaining bone density into middle age are pivotal for mitigating osteoporosis risk [4]. Notably, a 10% increase in peak bone mass can delay the onset of osteoporosis by up to 13 years [5]. Factors that influence peak bone mass include genetics, calcium and vitamin D intake, and physical activity [6].

Osteoporosis is a systemic bone disease characterized by reduced bone mass and microstructural deterioration, heightening bone fragility and fracture susceptibility [7]. The disease results from an imbalance between bone formation and resorption, with the latter predominating. Osteoporosis prevalence generally increases with age [8], affecting approximately 1 in 3 women and 1 in 5 men aged older than 50 years [7]. A systematic review and meta-analysis estimated the global prevalence of osteoporosis to be 18.3%, based on a cohort of 103,334,579 individuals [9]. The analysis encompassed 86 studies that involved participants aged 15 to 105 years [9]. In Kuala Lumpur, Malaysia, a cross-sectional study reported a prevalence of 12.3% among 786 adults aged 40 years and older

[10]. By 2050, the hip fracture incidence in Malaysia is projected to increase to 3.55 times that in 2018 [11]. In China, a study involving 9826 women aged 40 years and older reported a slightly higher osteoporosis prevalence of 20.6% [12], while Korea showed a prevalence of 38% among women aged 50 years and older in a sample of 4011 individuals [13]. Preventive measures against osteoporosis include optimizing peak bone mass during adolescence, maintaining bone density in adulthood, and mitigating age-related bone loss [14,15].

Lifestyle factors, such as dietary calcium intake, vitamin D status, and weight-bearing exercise, significantly influence bone health. Calcium plays a crucial role in maximizing bone density and strength during growth and development [6]. Adequate calcium intake is important for achieving optimal peak bone mass and promoting bone health, whereas insufficient intake increases the risk of low BMD [16]. Vitamin D, which is synthesized through skin exposure to UV-B rays and obtained from dietary sources, is essential for calcium homeostasis and absorption [17,18]. Insufficient vitamin D status is a global concern and is exacerbated by environmental factors, clothing practices, sunscreen use, and weather variations [19]. High-impact and weight-bearing exercises, such as running and jumping, enhance bone strength [20]. However, studies in Malaysia have identified suboptimal dietary calcium intakes [21,22], insufficient vitamin D status [21-25], and low physical activity levels among adolescents [26].

Raising osteoporosis awareness among adolescents is important for reducing the risk of the disease later in life [27]. Despite its significance, research on osteoporosis knowledge among adolescents in Malaysia is limited, with such research predominantly focusing on adults and older populations [10,28]. One study highlighted deficiencies in osteoporosis knowledge and engagement in bone health practices among adolescents [29]. Specifically, adolescents and young adults often perceive other diseases as more serious than osteoporosis [29]. This underscores the need to increase awareness of bone health and osteoporosis among adolescents.

Educational programs targeting osteoporosis prevention hold significant potential for improving adolescent bone health [30]. A systematic review and meta-analysis conducted by Abdolalipour and Mirghafourvand [30] demonstrated that such programs positively influence adolescent osteoporosis prevention by improving dietary calcium intake, promoting preventive practices, and enhancing knowledge about and attitudes toward osteoporosis. Therefore, implementing initiatives that focus on adolescent osteoporosis prevention is paramount for fostering healthy lifestyles. Research consistently demonstrates that these educational interventions enhance knowledge, shape attitudes, and encourage dietary practices conducive to bone health [30]. In-depth individual and semistructured interviews with 60 young adults aged 17 to 30 years highlighted that while most seek bone health information on the internet, traditional sources such as parents, doctors, educators, and peers remain valuable [31]. Importantly, participants preferred educational programs that deliver concise and relatable messages and promote gradual lifestyle changes [31].

e-Books use computer technology to deliver information dynamically through sounds, graphics, images, animations, and videos, offering enriched content when compared to conventional books [32]. A literature review that assessed the effectiveness of e-books in student learning reported high effectiveness scores, which ranged from 80% to over 95% across multiple studies [32]. Furthermore, a study that compared e-books to traditional PowerPoint (Microsoft Corporation) methods in clinical teaching found that e-books enhance student satisfaction, improve teaching quality and methods, and increase student engagement [33]. This study aims to assess the effectiveness of an e-book with interactive multimedia features in increasing knowledge about and promoting healthy practices related to bone health among Malay adolescents in Kuala Lumpur, Malaysia.

Methods

Study Design and Participants

This study used an experimental design with purposive sampling to gather data from Malay adolescents aged 14 to 16 years who attended selected secondary schools in Kuala Lumpur, Malaysia. Without a control group, the chosen single-group experimental approach ensured uniform access to the educational material among all participants, aligning with ethical and practical considerations in academic research. Practical constraints within the school settings, such as challenges in recruiting a comparable control group and ensuring their nonexposure to the e-book, further supported the selection of this design. Despite inherent limitations in terms of internal validity, particularly threats related to the absence of a control group, this study represents an initial exploration of e-books as educational tools for adolescents.

Initially, invitations were extended to 14 schools, with 6 granting permission for participation following the dissemination of relevant information to homeroom teachers. Eligible participants were required to have access to electronic devices, such as mobile phones, tablets, or computers, with internet connectivity. Adolescents with health conditions, including visual or hearing impairments, autism spectrum disorder, attention-deficit/hyperactivity disorder, Down syndrome, cerebral palsy, dyslexia, aphasia, or physical disabilities, were excluded from this study.

Ethical Considerations

Ethical approval was obtained from the Universiti Kebangsaan Malaysia’s research ethics committee (reference code: UKM PPI/111/8/JEP-2022 - 139). The data collected in this study were anonymized by using a study-specific identification number. Further, participants were given a notebook worth RM 5 (US $1.12) as a token of appreciation.

Data Collection

The research information sheet and an informed consent and screening form were disseminated through a web-based platform (WhatsApp [Meta Platforms] messages with a document link) by homeroom teachers. Interested participants who met the eligibility criteria and obtained parental or guardian consent were contacted and provided with a link to access the pretest questionnaire via Google Forms. This questionnaire gathered sociodemographic information, assessed knowledge about osteoporosis, and collected data on physical activity levels.

After completing the pretest questionnaire, a video call session via Google Meet was scheduled to assess habitual dietary calcium intake. Participants were subsequently given access to an e-book on bone health and instructed to read it within 2 weeks. At the end of this period, participants completed a posttest questionnaire, which was almost identical to the pretest questionnaire but excluded sociodemographic information. Additionally, the posttest questionnaire included a section to assess participants' acceptance of the e-book. A second video call session via Google Meet was conducted to reassess participants' dietary calcium intake. The entire data collection process was conducted via the internet to minimize interference with school schedules.

Research Instruments

e-Book

The e-book, which consisted of 58 pages, was previously developed and validated by an expert panel [34]. It featured vibrant infographics and illustrations that covered the following seven subtopics: (1) "Let's Know Our Bones," (2) "Osteoporosis," (3) "Adolescents' Bone Health," (4) "Calcium," (5) "Vitamin D," (6) "Physical Activity & Exercise for Bone Strength," and (7) "7 Healthy Lifestyles for Bone Health." In addition, the e-book included a 5-minute summary video and a link to a short quiz.

Sociodemographic Profiles

The sociodemographic data collected included sex, date of birth, household income, and prior participation in a bone health or osteoporosis education program. Participants self-reported their body weight and height, and the BMI was calculated by dividing weight by the square of height. BMI-for-age was analyzed by using WHO (World Health Organization) AnthroPlus version 1.0.4 (WHO), with classifications based on WHO cutoff points [35].

Osteoporosis Knowledge

Participants' knowledge about bone health and osteoporosis was assessed by using the Revised Osteoporosis Knowledge Test Questionnaire, which has demonstrated high internal consistency (Kuder-Richardson-20 values of 0.85 overall, 0.83 for the nutrition subscale, and 0.81 for the exercise subscale) and test-retest reliability (*r*=0.87) [36]. The questionnaire was confirmed through content validity, establishing it as a comprehensive instrument that reflects current research and assesses osteoporosis knowledge in adults [36]. We adapted this questionnaire to assess osteoporosis knowledge in adolescents. A previous study used this questionnaire to determine osteoporosis knowledge in Iranian adolescents [37].

The 32-item questionnaire was translated into Malay by using a back-translation method. Some questions (eg, those concerning the recommended amount of calcium and vitamin D intake) were modified to align with Malaysian dietary guidelines for adolescents [16]. One point was given for each correct answer, and 0 points were given for incorrect or "Do not know" responses. Each participant's total score was then converted into a percentage and classified as a high (>80%), medium (60% - 80%), or low (<60%) knowledge level based on previous osteoporosis research [38].

Practices Related to Bone Health

Dietary calcium intake was assessed by using a food frequency questionnaire (FFQ) adapted from a previous study on postmenopausal women in Malaysia [39]. Notably, there was limited availability of FFQs tailored for adolescents in Malaysia. This FFQ, which moderately correlated with a 3-day food record (*r*=0.563) [39], encompassed 78 food items. Administration of the FFQ was conducted through web-based video call interviews. Participants reported their frequency of consumption (daily, weekly, or monthly) and estimated portion sizes for each food item. The total calcium intake for each participant was calculated by multiplying frequency of consumption; portion sizes (g); and calcium content per 100 g, which was derived from the Malaysian food database [40].

Physical activity levels were assessed by using the Physical Activity Questionnaire for Adolescents (PAQ-A) [41]. The questionnaire was previously translated into Malay and demonstrated a low correlation (*r*=0.23; *P*=.08) but high reliability (*r*=0.72; *P*<.001) when compared to pedometer data [42]. A study conducted in Poland demonstrated a strong correlation between PAQ-A scores and accelerometer data (*r*=0.94; *P*<.01) [43].

The PAQ-A consists of 9 items that evaluate the participants' physical activity involvement over the past 7 days. Each item is rated on a 5-point scale, ranging from 1 (indicating a low level of physical activity) to 5 (indicating a high level of physical activity).

Acceptance of the e-Book

Acceptance of the e-book was evaluated by using a questionnaire adapted from a study that assessed physical information leaflets for pregnant women [44]. The assessment focused on the following three domains: content, graphics, and design. The level of acceptance was determined based on the percentage of responses within each domain. Although the instrument was initially developed for evaluating physical information leaflets (ie, it may not directly align with e-books), the assessed domains (content, graphics, and design) remain pertinent for evaluating educational materials. In this study, acceptance of the e-book served as a secondary outcome.

Statistical Analysis

Data were analyzed by using IBM SPSS Statistics software (version 26.0; IBM Corp). The normality of continuous data was assessed by using the Shapiro-Wilk test. Descriptive statistics were reported as means and SDs for normally distributed data or medians and IQRs for nonnormally distributed data. Categorical variables were summarized as frequencies and percentages. The Wilcoxon signed rank test was used to compare pre- and postintervention scores of knowledge, physical activity, and calcium intake, due to the nonnormal distribution of the data. For categorical variables, associations and comparisons were assessed by using the chi-square test or McNemar test. A *P* value of <.05 was considered statistically significant.

Results

Sociodemographic Profiles

A total of 72 participants (age: mean 15, SD 0.74 y) were enrolled in this study, and no dropouts were recorded (Table 1). The majority of the participants were female (n=51, 71%). The household income distribution was nearly evenly split among the low-income (n=23, 32%), middle-income (n=23, 32%), and high-income (n=26, 36%) categories. Most participants (n=51, 71%) were within the normal weight range, with a mean BMI of 20.9 (SD 4.5) kg/m^2. Only 1 participant reported prior education on bone health.

Table . Sociodemographic profiles and physical characteristics of participants (N=72).

Parameter		Value
Age (y), mean (SD)		15.0 (0.74)
Sex, n (%)		
	Male	21 (29)
	Female	51 (71)
Household income (RM[a]), n (%)		
	Low (<4850)	23 (32)
	Middle (4850 - 10,959)	23 (32)
	High (>10,959)	26 (36)
Weight (kg), mean (SD)		53.2 (13.3)
Height (m), mean (SD)		1.59 (0.07)
BMI (kg/m^2), mean (SD)		20.9 (4.5)
BMI category, n (%)		
	Thinness (<−2 SDs)	6 (8)
	Normal (≥−2 SDs)	51 (71)
	Overweight (>+1 SD)	9 (13)
	Obese (>+2 SDs)	6 (8)
Attending bone health education program, n (%)		1 (1)

[a] A currency exchange rate of RM 1=US $0.22 is applicable.

Osteoporosis Knowledge

The educational intervention significantly improved participants' knowledge of osteoporosis; the median knowledge score increased from 40.6% (IQR 31.3%-46.9%) in the pretest to 71.9% (IQR 53.9%-81.3%) in the posttest (*P*<.001; Table 2). Before the intervention, the majority of the participants demonstrated low levels of knowledge (69/72, 96%). There was a notable improvement after the intervention, with 38% (27/72) achieving moderate knowledge and 32% (23/72) reaching a high level of knowledge.

Table 3 presents the percentages of correct and incorrect responses ("False" or "Do not know") before and after exposure to the educational materials. Significant improvements were observed across all knowledge domains. Notably, 36% (26/72) of participants remained unaware that aging increases the risk of osteoporosis. Similarly, a small proportion of participants did not recognize the benefits of aerobic dancing for bone health (8/72, 11%), the fact that cheese is a good source of calcium (8/72, 11%), and that adolescence is a critical period for building strong bones (2/72, 3%).

Table . Osteoporosis knowledge before and after the educational intervention (N=72).

Osteoporosis knowledge		Pretest	Posttest	*P* value
Score (%), median (IQR)		40.6 (31.3-46.9)	71.9 (53.9-81.3)	<.001[a]
Knowledge classification, n (%)				.34[b]
	High (score: >80%)	0 (0)	23 (32)	
	Moderate (score: 60% - 80%)	3 (4)	27 (38)	
	Low (score: <60%)	69 (96)	22 (31)

Table . Analysis of osteoporosis knowledge questions before and after the educational intervention (N=72).

Questions		Pretest (correct), n (%)	Posttest (correct), n (%)	Pretest (incorrect), n (%)	Posttest (incorrect), n (%)	*P* value
Domain: risk factors of osteoporosis						
	1. Eating a diet low in dairy products	40 (56)	54 (75)	32 (44)	18 (25)	.01
	2. Being menopausal; "change of life"	26 (36)	50 (69)	46 (64)	22 (31)	<.001[a]
	3. Having a parent or grandparent who has osteoporosis	29 (40)	56 (78)	43 (60)	16 (22)	<.001[a]
	4. Being a White or Asian woman	5 (7)	28 (39)	67 (93)	44 (61)	<.001[a]
	5. Being an elderly	43 (60)	46 (64)	29 (40)	26 (36)	.73
	6. Having ovaries surgically removed	10 (14)	41 (57)	62 (86)	31 (43)	<.001[a]
	7. Taking cortisone (steroids; eg, prednisone) for a long time	25 (35)	43 (60)	47 (65)	29 (40)	.001
	8. Being overweight	33 (46)	53 (74)	39 (54)	19 (26)	.001
	9. Having an eating disorder	34 (47)	53 (74)	38 (53)	19 (26)	.003
	10. Consuming more than 2 alcoholic drinks per day	37 (51)	62 (86)	35 (49)	10 (14)	<.001[a]
	11. Smoking on a daily basis	38 (53)	55 (76)	34 (47)	17 (24)	.003
Domain: exercise						
	12. To strengthen bones, it is recommended that a person exercises at a moderately intense level for 30 min a day at least.... (answer: 7 days a week)	3 (4)	26 (36)	69 (96)	46 (64)	<.001[a]
	13. Exercise makes bones strong, but it must be hard enough to make breathing.... (answer: much faster, but talking is possible)	35 (49)	54 (75)	37 (51)	18 (25)	.001
	14. Which of the following activities is the best way to reduce a person's chance of getting osteoporosis? (answer: walking briskly)	6 (8)	25 (35)	66 (92)	47 (65)	<.001[a]

Questions		Pretest (correct), n (%)	Posttest (correct), n (%)	Pretest (incorrect), n (%)	Posttest (incorrect), n (%)	*P* value
	15. Which of the following activities is the best way to reduce a person’s chance of getting osteoporosis? (answer: lifting weights)	8 (11)	28 (39)	64 (89)	44 (61)	<.001[a]
	16. Which of the following activities is the best way to reduce a person’s chance of getting osteoporosis? (answer: jogging or running)	58 (81)	70 (97)	14 (19)	2 (3)	.004
	17. Which of the following activities is the best way to reduce a person’s chance of getting osteoporosis? (answer: aerobic dancing)	59 (82)	64 (89)	13 (18)	8 (11)	.38
Domain: calcium & vitamin D						
	18. Which of these is the best source of calcium? (answer: cheese)	52 (72)	64 (89)	20 (28)	8 (11)	.12
	19. Which of these is the best source of calcium? (answer: canned sardines)	14 (19)	44 (61)	58 (81)	28 (39)	<.001[a]
	20. Which of these is the best source of calcium? (answer: broccoli)	37 (51)	53 (74)	35 (49)	19 (26)	.005
	21. Which of these is the best source of calcium? (answer: yogurt)	56 (78)	67 (93)	16 (22)	5 (7)	.003
	22. Which of these is the best source of calcium? (answer: ice cream)	6 (8)	35 (49)	66 (92)	37 (51)	<.001[a]
	23. Which of these is the best source of calcium? (answer: almonds)	19 (26)	39 (54)	53 (74)	33 (46)	.001
	24. Which of the following is the recommended amount of calcium intake for an adolescent? (answer: 1300 mg daily)	16 (22)	54 (75)	56 (78)	18 (25)	<.001[a]

Questions	Pretest (correct), n (%)	Posttest (correct), n (%)	Pretest (incorrect), n (%)	Posttest (incorrect), n (%)	*P* value
25. How much milk must an adolescent drink to meet the recommended amount of calcium? (answer: 3 or more glasses daily)	18 (25)	47 (65)	54 (75)	25 (35)	<.001[a]
26. Which vitamin is required for absorption of calcium? (answer: vitamin D)	37 (51)	55 (76)	35 (49)	17 (24)	.003
27. Which is the best source of the vitamin required for the absorption of calcium? (answer: sunlight)	25 (35)	51 (71)	47 (65)	21 (29)	<.001[a]
28. Which is the best food source of the vitamin required for the absorption of calcium? (answer: salmon)	15 (21)	42 (58)	57 (79)	30 (42)	<.001[a]
29. Which of the following is the recommended amount of the vitamin required for the absorption of calcium for an adolescent? (answer: 15 µg daily)	18 (25)	47 (65)	54 (75)	25 (35)	<.001[a]
Domain: general knowledge on bone health					
30. When is the best time to build strong bones? (answer: adolescence)	67 (93)	70 (97)	5 (7)	2 (3)	.45
31. Osteoporosis can be diagnosed by.... (answer: DXA[b] scan)	42 (58)	58 (81)	30 (42)	14 (19)	.002
32. Once you have osteoporosis.... (answer: you can take medication to treat it)	19 (26)	42 (58)	53 (74)	30 (42)	<.001[a]

[a] McNemar test.

[b] DXA: dual-energy x-ray absorptiometry.

Practices Related to Bone Health

No significant differences were observed in dietary calcium intake (*P*=.31) and physical activity levels (*P*=.09) among adolescents following the intervention. Most participants exhibited inadequate calcium intake before (61/62, 98%) and after (61/62, 98%) the intervention. Similarly, a high proportion of participants maintained low levels of physical activity before (51/62, 82%) and after (48/62, 77%) the education intervention (Table 4).

Table . Practices related to bone health among participants (n=62).

Practices		Pretest	Posttest	*P* value
Calcium intake (mg), median (IQR)		575.8 (472.5-688.0)	585.9 (490.9-754.7)	.31[a]
Physical activity level (score), median (IQR)		2.2 (1.9-2.6)	2.3 (1.9-2.9)	.09[a]
Calcium intake classification, n (%)				>.99[b]
	Adequate (>1300 mg)	1 (2)	1 (2)	
	Inadequate (<1300 mg)	61 (98)	61 (98)	
Physical activity level classification, n (%)				.53[b]
	High (score: 4 - 5)	2 (3)	2 (3)	
	Moderate (score: 3)	9 (15)	12 (19)	
	Low (score: 1 - 2)	51 (82)	48 (77)	

[a] Wilcoxon signed rank test.

[b] McNemar test.

Acceptance of the e-Book

Table 5 shows participants’ feedback on the e-book. Overall, 97% (70/72) reported understanding the e-book content, with 71% (63/89) of responses (for the “Reasons for good understanding” question, participants could choose multiple responses) indicating that simple and easy-to-understand language facilitated comprehension. Furthermore, 93% (67/72) of participants emphasized the importance of graphics in the e-book, and nearly all participants (71/72, 99%) found the visuals attractive. Additionally, 78% (56/72) agreed that the color combination enhanced their reading experience, while most adolescents considered the layout of the pictures (60/72, 83%) and the font size (66/72, 92%) to be appropriate.

Table . Acceptance of the e-book on bone health among participants (N=72).

Evaluation aspects		Participants, n (%)
Understanding		
	Good understanding	70 (97)
Reasons for good understanding[a]		
	Simple and easy-to-understand sentence	63 (71)
	Appropriate words/terms used	17 (19)
	Attractive e-book	4 (5)
	Concise and precise	3 (3)
	Many photos/diagrams	2 (2)
Graphics importance		
	Yes	67 (93)
Attractiveness of graphic		
	Attractive	71 (99)
Color influenced reading		
	Yes	56 (78)
Appropriate picture layout		
	Yes	60 (83)
Appropriate font size		
	Yes	66 (92)

[a] Participants could choose multiple responses for this particular question. As such, the n values here refer to the number of responses, and the percentages were calculated by using the total number of these responses as the denominator (N=89).

Discussion

Osteoporosis Knowledge

This study demonstrates the effectiveness of an e-book–based educational intervention in enhancing adolescents' knowledge of bone health and osteoporosis. Our findings align with a meta-analysis of 18 studies, which reported significant differences in osteoporosis knowledge among adolescents between educational intervention groups and control groups [30]. Similar improvements have been observed across various populations, including adolescents [45], health care professionals [46], university students and academicians [47,48], and patients with osteoporosis [49]. Given the critical importance of maximizing peak bone mass during adolescence, implementing educational programs is highly justified [31].

Educational initiatives using diverse approaches and methods have consistently proven effective in increasing knowledge [45]. Web-based learning platforms offer flexible and accessible avenues for knowledge acquisition. Furthermore, leveraging technological advancements, such as those related to text, audio, and visuals, enhances information dissemination. This facilitates the development of interactive learning tools, such as images and videos, which effectively convey critical aspects of osteoporosis, such as nutrition and weight-bearing exercises [50].

Practices Related to Bone Health

Despite significant gains in knowledge, this study did not observe notable improvements in dietary calcium intake and physical activity among adolescents after the intervention. Most adolescents (61/62, 98%) exhibited inadequate dietary calcium intake, with the median daily intakes before (median 576, IQR 473-688 mg/d) and after (median 586, IQR 491-755 mg/d) this study being below the recommended 1300 mg/d [16]. This trend aligns with findings from a previous study of Malaysian adolescents, in which all participants (N=794) had inadequate calcium intakes (calcium intake: mean 377.4, 95% CI 365.1-389.7 mg/d) [22]. Similar inadequate calcium intakes among adolescents have been reported globally, including in Morocco (calcium intake: mean 522, SD 297 mg/d) [51], Brazil (calcium intake: mean 618.2, 95% CI 570.8-665.5 mg/d) [52], and the United States (calcium intake: mean 962, SD 478 mg/d) [53], indicating a widespread issue of low dietary calcium intake among adolescents. Adolescents appear to consume limited amounts of calcium-rich foods, particularly dairy products [51].

This study also highlighted low physical activity levels among participants, with median scores of 2.2 (IQR 1.9-2.6) during the pretest and 2.3 (IQR 1.9-2.9) during the posttest. This finding is consistent with a previous study of 13-year-old adolescents (n=289) in Malaysia, where low physical activity levels were reported (mean 2.01, SD 0.03) [21]. Again, our findings align with global trends, showing that many adolescents do not meet recommended physical activity levels. For instance, the WHO reported that globally, 81% of adolescents aged 11 to 17 years are insufficiently physically active [54]. Similar trends were noted in Portugal [55], Sweden [56], China [57], and Korea [58], of which all indicated low physical activity levels among adolescents. For instance, Marques et al [55] reported that in a sample of 520,533 participants, less than 20% of adolescents in Portugal participated in physical activity every day, and nearly 20% never engaged in any form of physical activity. Sedentary behaviors and insufficient physical activity negatively impact bone health and overall well-being.

Integrating Knowledge Into Behavior Changes

The gap between increased knowledge and unchanged health behaviors suggests that knowledge alone may not suffice to promote positive practices. Addressing both knowledge and bone health practices simultaneously is essential. This underscores the need for a comprehensive approach that integrates knowledge acquisition and behavior change techniques to foster optimal adolescent bone health practices. Our findings contrast with previous studies that demonstrated favorable impacts of educational interventions on behaviors such as calcium intake and physical activity among adolescents [59-61]. These disparities could be due to variations in the educational methodologies, particularly in facilitating behavior changes [59]. Direct educational approaches, such as interactive sessions that promote engagement and motivation, have shown promising results in improving adolescents' nutritional practices and physical activity levels [49,60,62].

It is worth noting that our intervention lasted for only 2 weeks, whereas previous studies implemented interventions over 2 to 3 months [60-62]. Behavior changes often require an extended period to be effectively integrated into daily routines [63]. The transtheoretical model of behavioral change suggests that behavior modification is a dynamic and individualized process involving various stages, including precontemplation, contemplation, preparation, action, and maintenance [64]. Therefore, extending the intervention period is essential to fully observe and understand the intervention's effects and assess its sustainability.

Nevertheless, a longer intervention alone does not guarantee sustainable behavior change. Incorporating behavior change theories and techniques, such as goal setting, self-monitoring, and feedback, may enhance the intervention's effectiveness. These techniques could facilitate the translation of knowledge into sustained behavior changes by actively engaging adolescents in their lifestyle practices. Additionally, using interactive elements, such as videos, quizzes, and simulations within e-books, can enhance the learning experience and support effective behavior change [65]. To ensure the long-term sustainability of the intervention, future studies should include systematic follow-up assessments to measure the retention of bone health–related knowledge and behaviors. Identifying barriers and facilitators to the ongoing use of the e-book, such as user engagement and perceived relevance, is also essential.

Acceptance Toward the e-Book

The e-book used in this study received positive feedback from adolescents, as they found it understandable, visually attractive, and well designed in terms of graphics and text size. Effective e-books should incorporate structured content and multimedia elements, such as sounds, graphics, images, text, and animations, to create an engaging and interactive learning experience [32]. e-Books can enhance adolescents' understanding by using visual elements, including animated images, to convey the information more engagingly [66]. Incorporating interactive multimedia elements in e-books makes learning exciting, meaningful, and inspiring for adolescents [67]. Special animations and effects, such as graphics and sounds, effectively capture adolescents' attention in educational settings.

Strengths and Limitations

This study is the first to assess Malay adolescents' knowledge and practices related to bone health following an educational intervention in Malaysia. The findings suggest that the e-book is effective for health promotion among adolescents. These results provide valuable insights for planning strategies to promote bone health among adolescents and the wider community, such as through the use of e-books.

Study limitations include the absence of a control group and uneven proportions of male and female respondents, which could have introduced bias. Additionally, the osteoporosis knowledge questionnaire and dietary calcium intake assessment evaluation tools have yet to be validated in the studied population. Furthermore, this study focused solely on calcium intake and physical activity, excluding other essential factors, such as vitamin D intake. The short intervention period also limited the ability to evaluate long-term behavior changes. Future studies should extend the intervention duration and include a broader range of bone health practices to provide a more comprehensive assessment.

Recommendations for Future Studies

Future research should focus on enhancing the e-book's content by incorporating more practical elements, such as easy-to-prepare recipes for calcium-rich foods and information on simple bone-health exercises. Integrating diversified and interactive educational content, including videos, quizzes, and simulations, can make learning more engaging and impactful. Such content can aim to engage adolescents and effectively promote the practical application of knowledge. To better foster sustained behavior changes, future studies should also consider extending the duration of the intervention period. Further, translating the e-book into other languages would increase its accessibility and cater to Malaysia's diverse population. Moreover, conducting similar studies among non-Malay adolescents would offer a broader understanding of bone health practices across different ethnic groups in Malaysia.

Conclusions

The developed e-book on bone health effectively increased knowledge related to bone health and was well received by Malay adolescents within our sample. However, the intervention did not significantly influence bone health practices, including dietary calcium intake (P=.31) and physical activity levels (P=.09). Additional strategies that integrate knowledge enhancement with practical demonstrations, interactive activities, and targeted approaches are necessary to promote the adoption of healthy behaviors for optimal bone health.

Acknowledgments

We would like to express our gratitude to all participants who participated in this study. Funding support was provided by research grants from Universiti Kebangsaan Malaysia (Dana Mutiara 2023, Faculty of Health Sciences, and GP-2021-K016325).

Conflicts of Interest

(JMIR Pediatr Parent 2024;7:e66676) doi:10.2196/66676

In “Assessing the Racial and Socioeconomic Disparities in Postpartum Depression Using Population-Level Hospital Discharge Data: Longitudinal Retrospective Study” JMIR Pediatr Parent 2022;5(4):e38879 the authors noted 4 errors.

In “Results”, first paragraph, the numbers in parentheses “(66,939/160,066)” have been revised to “(65,028/160,066)”, as follows:

> *Of the study population, 40.63% (65,028/160,066) were White,...*

In “Results”, first paragraph, the numbers in parentheses “(26,360/160,066, 16.47%)” have been revised to “(12,658/48,953, 25.86%)”, as follows:

> *Among all racial groups, the Black population had the highest proportion of individuals living in areas with <US $59,000 median household income (12,658/48,953, 25.86%).*

Under Results, third paragraph, the word “higher” has been revised to “lower”, as follows:

> *Married women have significantly lower odds of PPD than women who were divorced (OR 1.99, 95% CI 1.71-2.31), legally separated (OR 1.97, 95% CI 1.60-2.41), single (OR 1.45, 95% CI 1.38-1.51), or widowed (OR 2.96, 95% CI 1.82-4.64).*

Under Results, third paragraph, the word “lower” has been replaced by “higher” in the sentence:

> *Women living in areas with a median household income <US $46,000 have higher odds of PPD than women living in areas with median household income >US $59,000 (OR 0.79, 95% CI 0.73-0.85).*

The correction will appear in the online version of the paper on the JMIR Publications website on October 9, 2024, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

This Research Letter describes the increasing trend of almost-constant social media use among California adolescents and the association with serious psychological distress, focusing on the influence of familial and experiential factors.

(JMIR Pediatr Parent 2024;7:e57041) doi:10.2196/57041

KEYWORDS

social media; socials; youth; adolescents; teens; teenager; mental health; mental illness; mental disease; mental illnesses; psychological distress; psychological; psychology

Introduction

Increasing recognition of the potential dangers of excessive social media use on mental health has led to numerous calls for restraint and associated legal cases, as highlighted by the recent advisory issued by the US Surgeon General [1-3]; however, these dangers remain understudied. We examined social media use trends between 2019 and 2021 among adolescents in California. We further examined the association between almost-constant social media use and psychological distress using 2021 data, controlling for familial dynamics and adverse childhood experiences (ACEs), which are predictors of mental health [4] but have largely been overlooked in previous studies.

Methods

Survey and Data Collection

We used the California Health Interview Survey (CHIS) 2019-2021 data sets [5] for adolescents aged 12-17 years to examine trends in social media use. For a regression analysis examining the association between almost-constant social media use and psychological distress among adolescents, we used the 2021 data set with responses from 24,453 households, including 1169 participating adolescents. The CHIS randomly selects one adult to interview in each randomly sampled household, wherein households are selected using a geographically stratified address-based sample design. Following parental permission, surveys are conducted directly with a randomly sampled adolescent in the household. The survey, conducted either on the web or by telephone, includes a comprehensive set of health-related questions. Respondents are asked to report on typical daily use of social media on the following scale: less than a few times a day, a few times a day, many times a day, and almost constantly or more. We categorized this scale into a two-category variable wherein the category “almost constantly or more” is referred to as almost-constant social media use. Psychological distress was measured using the Kessler 6 series [6]; for this analysis, we examined the category of likely having had serious psychological distress in the past year. Family connection was measured through a series of questions, including how often the adolescent felt they were able to talk to family about their feelings, how often they felt family stood by them during difficult times, how often they felt safe and protected by the adult at home, and how often they had at least two nonparent adults taking a genuine interest in them. Adolescents responding “little to never” to any of these questions were assigned to a group characterized by little to no family connection. Adolescents responding having had at least one ACE were assigned “yes” to the ACEs variable.

Statistical Analysis

Demographic variables, including age, gender, race and ethnicity, and socioeconomic status, were included in the analysis as covariates. The data were weighted to account for the complex survey design and to generate population-level estimates. We used multivariate logistic regression models to examine the association between almost-constant social media use and serious psychological distress, controlling for demographic characteristics, family factors, and ACEs. All analyses were conducted using STATA 16.1.

Ethical Considerations

This study used deidentified, publicly available data, which does not constitute human subjects research as defined by regulation 45 CFR 46.102 of the US Department of Health and Human Services [7], and thus does not require ethics board approval. All CHIS respondents receive an initial survey invitation letter with a US $2 preincentive. Participation is voluntary and all participants provide informed consent before participating in the survey.

Results

Almost-constant social media use for the youngest teens (aged 12-14 years) increased significantly between 2019 and 2021, whereas this increase was not noted for older teens (aged 15-17 years). Among 12-14–year-old females, the rate of almost-constant use was 18.1% (95% CI 11.2-25.0) in 2019, 22.2% (95% CI 15.4-29.1) in 2020, and 28.9% (95% CI 20.8-37.0) in 2021; among 15-17–year-old females, the rate of almost-constant use was 33.0% (95% CI 25.8-40.2) in 2019, 26.9% (95% CI 20.8-32.9) in 2020, and 29.1% (95% CI 20.8-37.3) in 2021. Among male adolescents, almost-constant social media use increased significantly between 2019 and 2021 for both age groups. Among 12-14–year-old males, the rates were 11.9% (95% CI 6.2-17.6) in 2019, 22.7% (95% CI 16.4-28.9) in 2020, and 23.7% (95% CI 18.4-29.0) in 2021; among 15-17–year-old males, the rates were 14.1% (95% CI 9.8-18.4) in 2019, 22.4% (95% CI 17.3-27.6) in 2020, and 28.9% (95% CI 22.9-34.9) in 2021. By 2021, there were no longer significant differences in almost-constant social media use according to age group.

The rates of almost-constant social media use were the highest for teens living in poverty, those who have experienced ACEs, those who reported little to no family connection, and those who reported serious psychological distress (Table 1).

Regression analyses suggested a significant positive association between almost-constant social media use and psychological distress controlling for ACEs, family connection, and demographics (Table 2).

Table . Association of characteristics of adolescents (12-17 years old) with almost-constant social media use from the California Health Interview Survey 2021 (N=1169).

Characteristic		Almost-constant social media use, % (95% CI)
Total (all adolescents)		27.62 (24.19-31.35)
Age (years)		
	12-14	26.23 (21.48-31.61)
	15-17	28.98 (24.30-34.16)
Gender[a]		
	Female	28.97 (23.61-35.00)
	Male	26.35 (22.40-30.72)
Federal Poverty Level (%)		
	<300	33.19 (27.65-39.23)
	≥300	22.61 (19.26-26.35)
Race [b]		
	Asian	28.66 (21.02-37.76)
	Latino	30.23 (24.95-36.09)
	Black, African American, and other	22.72 (12.81-37.04)
	Two or more	27.94 (17.60-41.31)
	White	23.17 (18.21-29.01)
Serious psychological distress		
	Yes	37.36 (31.09-44.09)
	No	22.63 (19.27-26.38)
Adverse childhood experiences		
	Yes	36.17 (30.72-42.01)
	No	20.95 (17.48-24.91)
Family connection		
	Little to none	34.02 (28.47-40.04)
	More than little	22.21 (18.42-26.52)

[a] While the California Health Interview Survey collects data on nonbinary gender, for sample size considerations, we report only male and female categories here.

[b] The sample size was too small to produce reliable estimates for the Black/African American population alone, American Indian or Alaska Native, and Native Hawaiian or Pacific Islander populations.

Table . Association between almost-constant social media use and serious psychological distress among adolescents (aged 12-17 years) from the California Health Interview Survey 2021 (N=1169).

Variable		Adjusted odds ratio (95% CI)	*P* value
Social media use per day			.003
	Almost constant	1.673 (1.204-2.323)	
	Less than almost constant	reference	
Age (years)			.003
	12-14	reference	
	15-17	1.710 (1.205-2.429)	
Gender[a]			.005
	Female	1.597 (1.155-2.209)	
	Male	reference	
Federal Poverty Level (%)			.92
	<300	1.017 (0.709-1.460)	
	≥300	reference	
Race [b]			
	Asian	0.641 (0.377-1.089)	.10
	Latino	0.674 (0.469-0.967)	.03
	Black, African American, and other	0.807 (0.357-1.824)	.60
	Two or more	1.133 (0.617-2.079)	.68
	White	reference	
Adverse childhood experiences			<.001
	Yes	2.403 (1.736-3.327)	
	No	reference

	Little to none	2.171 (1.502-3.139)	
	More than little	reference	

[a] While the California Health Interview Survey collects data on nonbinary gender, for sample size considerations, we report only male and female categories here.

[b] The sample size was too small to produce reliable estimates for the Black/African American population alone, American Indian or Alaska Native, and Native Hawaiian or Pacific Islander populations.

Discussion

Our work is the first to examine the association between social media use and psychological distress controlling for ACEs and the adolescent-reported level of family connection, both of which are significantly associated with psychological distress [4]. Even when controlling for these and other demographic variables, almost-constant social media use remained significantly associated with psychological distress. Our key limitation is the cross-sectional nature of the data. Other limitations include the analysis of self-reported data on social media use, which may be subject to recall or social desirability bias, and possible other confounders not included in the analysis. Our work is consistent with prior research that finds increasing trends in use of social media among the youngest teens [8] and potential adverse mental health impacts from high or almost-constant social media use [9-12].

Abstract

Background: Exposures to both negative and positive experiences in childhood have proven to influence cardiovascular, immune, metabolic, and neurologic function throughout an individual’s life. As such, adverse childhood experiences (ACEs) could have severe consequences on health and well-being into adulthood.

Objective: This study presents a narrative review of the use of digital health technologies (DHTs) and artificial intelligence to screen and mitigate risks and mental health consequences associated with ACEs among children and youth.

Methods: Several databases were searched for studies published from August 2017 to August 2022. Selected studies (1) explored the relationship between digital health interventions and mitigation of negative health outcomes associated with mental health in childhood and adolescence and (2) examined prevention of ACE occurrence associated with mental illness in childhood and adolescence. A total of 18 search papers were selected, according to our inclusion and exclusion criteria, to evaluate and identify means by which existing digital solutions may be useful in mitigating the mental health consequences associated with the occurrence of ACEs in childhood and adolescence and preventing ACE occurrence due to mental health consequences. We also highlighted a few knowledge gaps or barriers to DHT implementation and usability.

Results: Findings from the search suggest that the incorporation of DHTs, if implemented successfully, has the potential to improve the quality of related care provisions for the management of mental health consequences of adverse or traumatic events in childhood, including posttraumatic stress disorder, suicidal behavior or ideation, anxiety or depression, and attention-deficit/hyperactivity disorder.

Conclusions: The use of DHTs, machine learning tools, natural learning processing, and artificial intelligence can positively help in mitigating ACEs and associated risk factors. Under proper legal regulations, security, privacy, and confidentiality assurances, digital technologies could also assist in promoting positive childhood experiences in children and young adults, bolstering resilience, and providing reliable public health resources to serve populations in need.

Introduction

Exposures to both negative and positive experiences in childhood have proven to influence cardiovascular, immune, metabolic, and neurologic function throughout an individual’s life [1,2]. As such, adverse childhood experiences (ACEs) could have severe consequences on health and well-being into adulthood [3,4]. ACEs are defined as traumatic childhood events, including abuse (physical, emotional, or sexual), neglect (physical or emotional), household dysfunction, caregiver or parental loss, and experiences of trauma around other social determinants of health [5]. Repeated exposure to a broad variety of traumas in early childhood places particular strain on mental health and is correlated with illicit substance use disorders, depression, obesity, and increases in suicidal ideation into adulthood [6]. Due to recurrent stress response activation before the age of 18 years, children and young people with a history of multiple ACEs are at higher risk of developing neuropsychiatric and emotional disorders, including posttraumatic stress disorder (PTSD), anxiety or depression, attention-deficit/hyperactivity disorder (ADHD), and schizophrenia [7]. However, the relationship between ACEs and behavioral problems is sometimes characterized as bidirectional, with a disorder diagnosis preceding the incidence of ACEs [8]. Regardless of the bidirectional potential, estimates show that more than 50% of children and young people in the United States have reported experiencing at least 1 ACE before their 18th birthday, emphasizing a growing need for intervention, including the continued exploration of the role of positive childhood experiences (PCEs) [9].

Pressing the issue, the global COVID-19 pandemic influenced a marked rise in reported ACEs. A recent Adolescent Behaviors and Experiences Survey conducted by the Centers for Disease Control and Prevention found that 73% of high school–aged students reported experiencing at least 1 adverse event during the pandemic period [10]. The study found that exposed students had a significantly higher prevalence of mental health complaints and an increase in suicidal ideation as compared to adolescents reporting no ACEs [10]. In the wake of this escalation, a national emergency in child and adolescent mental health was declared by the American Academy of Child and Adolescent Psychiatry, the American Academy of Pediatrics, and the Children’s Hospital Association in late 2021 [11]. The advisory sheds light on the severe mental health consequences of the pandemic, noting the extraordinary weight of children and young people being forced to socially isolate and distance themselves from peers, cope with unprecedented grief, and adapt to digital learning environments [11]. Additionally, more than 140,000 children and young people were reported to have experienced the death of a parent or caregiver due to COVID-19 infection in the first year of the pandemic alone [12]. While associated concerns preceded the COVID-19 pandemic, recent exacerbation highlights the occurrence and related effects of adverse events on the mental health of children and young people as a critical public health issue.

Recent research efforts have focused on understanding how PCEs may help to counter the risks of ACEs [6,13]. Emerging evidence suggests that early access to safe, stable, nurturing environments; positive attachments with caregivers, peers, and teachers; interpersonal connection; opportunities for emotional growth; school engagement; and connection to culture and community are among PCEs linked to strengthening childhood resilience and overall health and well-being across the life span [14,15]. Such experiences aid in the vital development of a sense of belonging and connectedness, which often serve as a helpful buffer to the negative effects of ACEs [16].

As digital use by children and adolescents has exponentially increased over the past decade [17], the potential for digital health interventions is promising. The application of digital health technologies (DHTs) has the potential to assist in screening and mitigation of the profound impacts of early life experiences and improve the well-being of children and young people [18]. DHTs have been emerging as transformative solutions to challenges in health care delivery since the early 2000s and are considered to promote equitable, affordable, and universal access to patients and health care providers [19]. The technologies, such as mobile health (mHealth), health information technologies, wearable smart devices, wireless medical devices, personalized medicine, and telemedicine platforms, offer innovative tools to enhance population health and public health responses [20].

When used to mitigate the profound and long-lasting effects of adverse experiences on children and young people, comprehensive, trauma- and evidence-informed digital tools can increase treatment accessibility, strengthen prevention and screening resources, and bolster available support for individuals most vulnerable to ACEs. Given the ever-increasing ubiquity of digital tools, the distribution of DHTs has the potential to reach children and young people and their families on a more intimate level. The innovative development of DHTs for ACE intervention could open new therapeutic pathways for children and adolescents, and such DHTs could also serve as knowledge reservoirs for parents and caregivers to aid in promoting positive experiences in childhood, bolstering resilience [21]. As research examining the role of PCEs continues to grow, increased development of DHTs could provide new opportunities for novel approaches to trauma-informed care in both the clinical setting and in the home. With the help of resources and recommendations on demand, families could readily access personalized messages in the form of texts and multimedia aimed at countering the negative health effects associated with ACEs outside of the traditional clinical setting. This could alleviate several barriers to care, including financial constraints (ie, insurance and copay challenges), geographical or physical inaccessibility (ie, health care access in rural settings, transportation), additional childcare for large families, or inadequate health care resources (ie, provider shortages), providing immediate treatment from a distance [22].

Ultimately, promoting the use of DHTs expands care access and strengthens patient and family engagement. Accordingly, the objective of this literature review was to evaluate and identify means by which existing digital solutions may be useful in mitigating the mental health risk factors and consequences associated with the occurrence of adverse experiences in childhood and adolescence and preventing ACE occurrence, including by highlighting knowledge gaps or barriers for DHT implementation for vulnerable populations. We argue that DHTs could help to prevent and mitigate the lasting effects of ACEs on children and young people, bolstering resilience, promoting PCEs, and alleviating the burden of ACE-associated impacts on health and well-being into adulthood.

Methods

Search Strategy

We performed a search of existing literature, incorporating peer-reviewed studies that were identified from 3 databases (PubMed, SSRN, and Google Scholar) and published between August 2017 and August 2022, to allow for evaluation of the most recent applications of DHTs. Our search terms were used based on the thesaurus and keywords, including “digital health,” “adverse childhood experiences,” “artificial intelligence,” “domestic violence,” “abuse,” “mental health,” “family environment,” “COVID-19,” “suicide,” “depression,” “anxiety,” “social determinants of health,” “personal health library,” “precision medicine,” “substance abuse,” “alcohol use,” and “post-traumatic stress disorder.” Terms and keywords were combined to comprise search phrases, allowing for a more sensitive search. Search phrases included “the application of AI and DH to prevent ACEs,” “role of DH and AI for mental health,” “knowledge gap in digital health,” “significance of DH in mental health,” “specific AI solutions for ACE risks,” “DH interventions in adolescence,” “children who need special care,” “machine learning application,” and “electronic health record.” Additionally, reference lists from selected papers were searched for possible matches and inclusion.

Inclusion and Exclusion Criteria

Studies were included for review if they met the following eligibility criteria: (1) published from August 2017 to August 2022, (2) explored the relationship between digital health interventions and mitigation of negative health outcomes associated with mental health in childhood and adolescence, (3) examined prevention of ACE occurrence associated with mental illness in childhood and adolescence, and (4) conducted in the United States. Studies were excluded if they were not original research or were not available in the English language.

Study Selection, Data Extraction, and Analysis

The initial electronic database search generated papers whose titles or abstracts were collectively screened by 2 reviewers (RP and BMW) to ensure fit to the specified eligibility criteria. The following data were extracted: title, lead author, publication year, study purpose, study design, ACE risk factor indicated, and author’s conclusion. Extracted data were collated and stored on a Microsoft Excel spreadsheet (Microsoft Corp) coding matrix.

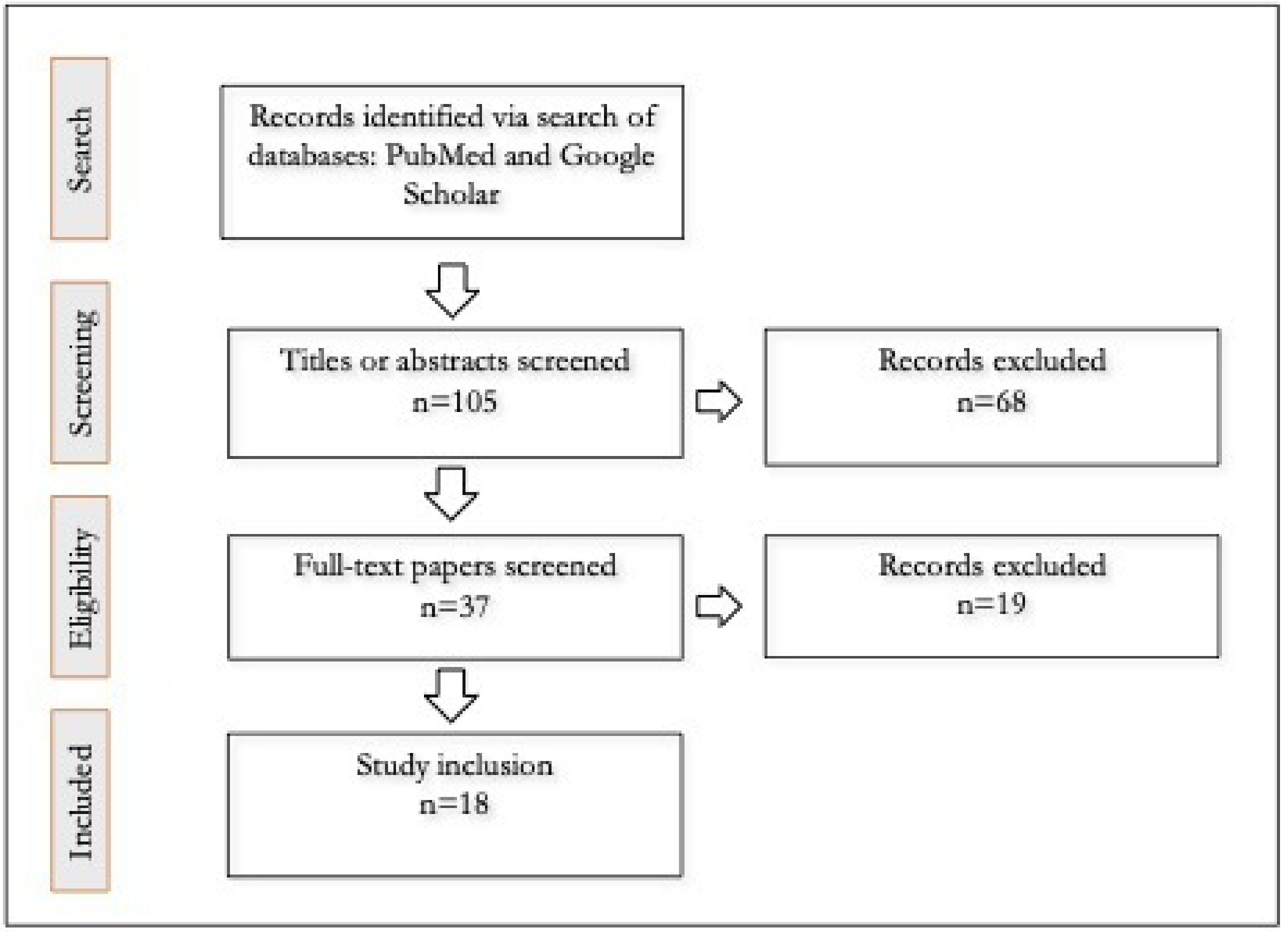
Results

Overview

The search of PubMed, SSRN, and Google Scholar and reference lists of each selected paper yielded a total of 105 results. In total, 87 studies were eliminated because they did not meet the inclusion criteria. After title or abstract screening and full-text review, a total of 18 studies were selected for data extraction and analysis, as demonstrated in Figure 1.

The oldest paper included in this study was published in August 2017, with others as recent as May 2022. Study characteristics and general information on papers selected for review are included and outlined in Multimedia Appendix 1. A total of 100% (18/18) of included papers positively reported the use of digital solutions for ACEs.

Figure 1. Paper selection process.



Use of DHTs for the Management of ACE-Related Mental Health Outcomes

Overall, 44% (8/18) of our examined papers reported the use of DHTs to identify indicators of mental illness and reduce the negative effects of such adverse experiences. Studies assessed the suitability, usability, and acceptability of digital health interventions for the management of mental health illness with findings in support of the effectiveness of computerized cognitive behavioral therapies [23-28]. Such tools are argued to help diagnose, predict, and prevent negative outcomes of mental health illness due to ACEs. Examined studies argue that digital solutions, such as educational mobile apps, directed at children and young people have the potential to be important assessment, management, and treatment tools to provide efficient access to health services and promote self-help in hours of need [23,25,28]. Similarly, another study found that children and young people responded well to structured digital peer-to-peer interactions and strength-based mHealth coaching [26]. Moreover, collective findings highlight the potential for the use of social media–based digital intervention for children and young people at risk of negative mental health outcomes associated with ACEs [27,28].

Posttraumatic Stress Disorder

Children exposed to traumatic ACEs are reported to have a higher incidence of PTSD compared to their peers without repeated stress [29,30]. One study from our search found promise in the use of artificial intelligence and longitudinal data to identify and treat children with PTSD as a result of childhood traumas [30]. Lekkas and Jacobson [30] found the use of geometric Global Positioning System data to measure daily minutes spent and the radius traveled away from home was an effective way to detect “avoidance symptoms” displayed by high-risk cohorts with a history of abuse and neglect. The study found that, without clinical predictors, the deployed passive monitoring tools successfully diagnosed PTSD more than 80% of the time [30].

Suicidal Behavior or Ideation

From our search, 22% (4/18) of selected studies characterized opportunities for DHTs, machine learning, and electronic health record restructuring to predict the suicidal risk in children and young people having experienced 1 or more ACEs.

Overwhelmingly, suicide rates are 30 times higher among adults with more than 4 ACEs, highlighting an urgent need for innovative solutions [31]. Findings from examined papers suggest that DHTs could play key roles in identifying predictors of suicidal behavior, violence, and unintentional injury. Chen and Chan [32] found that digital health interventions have great potential to reduce unintentional injury, violence, and suicide in children and young people who have witnessed or experienced 1 or more traumatic events. The study argues that future work should focus on intervention to increase access to comprehensive digital technologies for those who have experienced or witnessed abusive behaviors in childhood or adolescence [32]. Notably, conclusions from another investigation suggest that predictive models of suicide risk of children and adolescents, by using demographics, comorbidity diagnosis codes, laboratory test results, and medications from clinical records models, show good performances for estimation of short-term and long-term risks and identify significant predictors, which may assist in clinical practices [33].

Others found that DHTs can be used to successfully predict, and potentially prevent, suicide risk among adolescents [33-35]. One used machine learning to successfully detect 53% ‐ 62% of suicide-positive behavior with 90% specificity [34]. Findings support growing evidence that the innovative use of electronic health records can be useful in developing reliable predictive models for suicide risk among children and young people [34]. Similar findings were expressed by Walsh et al [35], whose findings further suggested that routinely collected clinical data can be leveraged to predict suicide risk in children and young people with a history of ACE with computational algorithms. However, it is important to note that these findings are not always generalizable on a global scale, as only a small proportion of existing digital platforms in low- and middle-income countries are evidence-based and frequently demonstrate low effectiveness due to factors such as societal mistrust [24]. As such, widespread adoption and scale-up of digital mental health interventions will require more rigor in research and study before widespread global implementation.

Anxiety or Depression

Anxiety is characterized by the reflection of internal feelings of discomfort expressed with uneasiness, and prolongation of these feelings can cause severe depression in children and young people [36]. Unfortunately, there are only a small number of studies available examining the correlation between ACEs and anxiety, with far fewer deciphering noticeable differences between anxiety and depression for children and young people having experienced 4 or more ACEs [36]. However, of the results from our search, 16% (3/18) indicated possible uses of digital health to support and care for children experiencing anxiety. Findings from one examined study suggest that digital interventions aimed at the improvement of anxiety symptoms in children and young people can be transformative in supplementing traditional treatment plans [37]. Khanna and Carper [37] found that digital mental health interventions, such as web- or cloud-based therapeutic programs, mobile apps, and virtual reality simulations, are reliable mitigation tools and should be used to supplement and maximize anxiety treatment completion.

This sentiment is echoed by both Williams and Fried et al [38,39], who also found a significant opportunity for the employment of digital interventions. Both argue that the development of mental health monitoring applications for anxiety and depression could allow for real-time recording of mental health symptoms, including perceived feelings and behaviors [38,39]. Conclusions suggest that population-wide use of such monitoring applications could reshape the clinical understanding and progression of mental health conditions, such as anxiety or depression, creating opportunities for targeted mitigation response [38,39].

Attention-Deficit/Hyperactivity Disorder

Children and young people experiencing the effects of ACEs are at heightened risk of developing behavioral disorders such as ADHD [40]. From our search, 16% (3/18) of examined studies highlight the use of digital therapeutic interventions for the improvement of ADHD. Studies found that game-based digital therapeutic devices, such as the Food and Drug Administration–approved EndeavorRx, support positive outcomes when used to treat ADHD among children aged 8 to 12 years without the need for pharmacological intervention [41]. Kollins et al [42] found that daily game-like interaction with a digital therapeutic program (AKL-T01) improved inattention in children and young people diagnosed with ADHD. Similarly, Fried et al [39] found that the use of a digital mindfulness application showed a marked reduction in inattentiveness and anxiety for children aged 6 to 12 years with a history of ADHD. Additionally, results from a survey administered during the 4-week pilot study found a correlation between sleep patterns and both stress levels and attention span [39]. These findings could help to inform appropriate management plans and highlight the potential for the continual development of game-like digital interventions designed to exercise memory training and neurofeedback [41,42]. These innovative applications not only provide clinicians with attention assessments by measuring key stimuli and response variabilities but also supply users with continual intervention by sharpening perseverance and self-efficacy skills [42].

Discussion

Principal Findings

Immense challenges exist in overcoming ACEs in children and young people. Physical, sexual, or emotional abuse in childhood can severely impact the health of children and young people. Children who have experienced or witnessed more than 3 related types of abuse are at high risk for self-destructive behaviors, including substance abuse, suicidal ideation, and overall poor resilience [43].

As screening can be time-consuming and difficult to implement on a broad-reaching scale, DHTs may provide a scalable approach to capturing vulnerability and resilience factors in real time. We argue findings from our review may suggest that incorporating DHTs for managing the mental health consequences of repeated exposure to childhood trauma shows promise for building childhood resilience.

Innovation

While arguably still in the early decades of meaningful implementation, there is pronounced potential for innovative digital technologies and interventions to identify indicators of mental illness and reduce the risk factors and negative effects of related adverse experiences. Mental illnesses related to ACEs are most commonly the result of enduring verbal, sexual, or physical abuse; neglect; parental separation or incarceration; familial substance abuse; domestic violence; poverty; peer rejection; and death or traumatic loss before age 18 years [44]. Additionally, many social determinants contribute to unfavorable familial conditions negatively affecting the health of children and young people, such as unemployment, food insecurity, single parenting, and unsafe neighborhood environments [44]. Support opportunities provided by DHTs supply health care providers with necessary mitigation tools for the extraction, processing, assessment, and analysis of patient-provided information for use in rapid response strategies [45-47]. Additionally, advancements in digital surveillance tools tasked with symptom-based geolocation could help pinpoint vulnerable communities for tailored mitigation, including comprehensive educational programs focused on the prevention of ACEs.

Perhaps harnessing the greatest potential are the innovation and scaling up of game-based therapeutic applications. As demonstrated in our results, these digital therapeutics have been shown to positively support the management and improvement of multiple mental health conditions (ie, PTSD, suicidal ideation, anxiety, depression, and ADHD) by engaging children and young people with unconventional treatment approaches [48]. For example, digital meditation and relaxation applications are therapeutic for children and young people with anxiety, depression, and sleeping problems, alleviating burdens related to increased stress factors and lack of adequate rest [39]. These technologies could also be used to facilitate resilience by promoting digital literacy and positive health information–seeking behavior and delivering precision health education or promotion. Digital interventions hold the potential to provide targeted resources to elevate PCEs, transforming early childhood experiences for those at the highest risk of facing adversity. DHTs may serve as a buffer against the effects of ACEs by broadening opportunities for exposure to positive experiences such as play, recognition, acceptance, praise, and other protective factors. Moreover, such digital technologies could prove to be advantageous in bolstering appointment and follow-up arrangements, patient screening and monitoring, and improvement of training and education for providers and decision makers. This bidirectional expansion could help bridge the gap between patient needs and care services.

Limitations

While this review highlights the strengths and successes of digital solutions for mitigating ACEs, it also helps uncover the need for further exploration of their actionability. Challenges related to addressing gaps in digital health literacy, high-speed internet access, confidentiality, reliability, and trust remain. Ethics and practice guidelines are needed, and questions remain regarding the level and quality of therapeutic involvement needed to maximize treatment to bolster resiliency and positive outcomes in youth. Moreover, underreporting of ACEs and subsequent lack of treatment of associated consequences remain barriers due to the sensitive, deeply personal nature of mental health illness [49]. The growing body of evidence supports and encourages the development of personalized patient-provider communications, the fostering of personal relationships, and the counteraction of misinformation as solutions to decrease uncertainty and bolster patient-provider trust [50-52]. Likewise, there is room for comprehensive DHTs tasked with the creation and amplification of tailored messaging to target populations who display hesitancy to openly discuss mental health concerns with care providers. These tools could offer comprehensive educational material during care visits, complementing the therapeutic relationship of interpersonal communication and treatment and helping to bridge the gap between patient and provider when discussing mental health.

Furthermore, training and ACE awareness or educational campaigns to bolster proficiency for health care professionals could be achieved through structured digital learning and mHealth technologies. With proper training, health care professionals would be adequately equipped to both assess and accurately report ACE-related findings and effectively communicate prevention and response strategies to patients at risk. Although DHTs harness the potential for the screening and prevention of ACEs, it is also imperative to facilitate equitable access to these digital tools for vulnerable, harder-to-reach communities. Special attention should be given to developing DHTs with the capability to navigate and transcend many social determinants of health. As previously mentioned, challenges related to high-speed internet access may prevent families from fully harnessing the potential of DHTs. With this in mind, a standard of DHT development should include the ability to access tools and resources offline. Moreover, contextual information should be made available at every literacy level to account for a range of understanding. Overall, vulnerable populations must be considered during policy development and decision-making before implementing any architecture.

There is also a growing need for transparency, explainability [53], and understanding of digital health infrastructure for children and young people, particularly for those with special needs. Technologies aimed at children and young people should be standardized, so that messaging is consistent across varying platforms and information systems, as standardization could aid in mitigating confusion among the public when navigating mental health illnesses and other health disparities. Adequate funding is needed for institutions of learning (ie, grade schools and universities) to offer courses on digital health literacy, health information–seeking behaviors, ACE risk factors or consequences, big data analytics, and artificial intelligence. Additionally, there is room for participation and infrastructure development from private sector stakeholders (eg, information and communication technology companies) to facilitate efficient operationalization and optimization of digital health initiatives. The progressive growth of DHTs, especially in preventing mental health issues, is warranted to make solutions more accessible to a broader range of those in need.

Conclusions

Successful development and deployment of digital solutions could reduce the consequences to mental health related to adverse childhood events; bolster childhood resilience; and influence future health policy, decision-making, and program implementation for ACE prevention and control [46,54].

From our findings, digital solutions, such as game-like mindfulness applications, have notably aided in the identification or treatment of PTSD, suicidal ideation, anxiety, depression, and ADHD in children at risk of or experiencing negative health effects associated with ACEs. While digital solutions should not be considered as a replacement for physical evaluation or treatment, the innovation of such tools could aid in identifying risk factors and preventing future complications and long-term illness or medical care dependence as a result of these conditions. We argue there is room for governmental and private sector stakeholder support of expansive, digital, open-source, modular DHTs with user-friendly graphical interfaces. Additionally, policy and data governance investments could support the tailored delivery of therapies and education efforts to ensure resource-limited populations have full access to these comprehensive technologies, preventing more severe negative outcomes.

Optimizing DHTs with the proper use of these technologies under regulatory control, screening, and prevention of the risks of ACEs can bolster public health response to mental health care for children and young people. Furthermore, consideration of the probable bidirectionality in the relationship between ACEs and mental health consequences when developing comprehensive digital tools could further help prevent associated impacts on well-being in adulthood, no matter the etiology of adversity. Regardless of origin or onset, prioritization of digital interventions targeting all underlying pathways could help to interrupt cycles of adversity and promote resilience for children experiencing mental illness. Future expansion of DHTs and their use could help bridge the gap between patients, providers, and researchers, increasing the number of PCEs and reducing associated morbidities and mortalities by enhancing screening and prevention of ACEs at earlier stages. Expanding and adopting such innovative, cost-effective digital solutions could have meaningful impacts on health care services for those affected by ACEs.

Authors' Contributions

BMW and RP conceptualized the study and drafted, reviewed, and edited the manuscript. NA and JAY reviewed and edited the manuscript. AS-N drafted, reviewed, and edited the manuscript; supervised the study; and acquired funding.

Abstract

Background: Managing type 1 diabetes in children and adolescents can be difficult for parents, health care professionals, and even patients. However, over the last decades, the quality of services provided to patients with diabetes has increased due to advances in IT.

Objective: This study aims to comprehensively document the range of IT tools used in the management of diabetes among children and adolescents, with a focus on identifying the technologies most commonly used based on their frequency. In addition, the study aims to explore relevant methodologies for developing diabetes technology and provide valuable information to developers by delineating essential phases of the design process.

Methods: The literature search was focused on MEDLINE (PubMed), Web of Science, and Google Scholar for relevant studies. Keywords such as "type 1 diabetes," "adolescents," "kids," "mHealth," "children," and "coaching" were combined using Boolean operators. The inclusion criteria were open access, English-language papers published between 2012 and 2023 focusing on patients younger than 18 years and aligned with our research goal. The exclusion criteria included irrelevant topics and papers older than 18 years. By applying the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) method, 2080 studies were recognized, and after selection, 33 papers were agreed upon between the researchers.

Results: Four primary categories were defined: types of IT, methodology identification, purpose identification, and feature determination. Among these, mobile health (mHealth) apps emerged as the predominant type of information, garnering 27 mentions. In particular, user-centered design was identified as the most prevalent methodology, cited 22 times. The primary purpose of self-monitoring blood glucose values was mentioned 20 times, while patient education was the highest among common characteristics, with 23 mentions.

Conclusions: Based on our research, we advocate for developers to focus on creating an mHealth app that integrates gamification techniques to develop innovative diabetes management solutions. This app should include vital functionalities such as blood glucose monitoring, strategies to improve hemoglobin A_{1c} levels, carbohydrate tracking, and comprehensive educational materials for patients and caregivers. By prioritizing these features, developers can enhance the usability and effectiveness of the technology, thereby better supporting children or adolescents with diabetes in their daily management endeavors.

type 1 diabetes; adolescents; children; parents; mHealth; information technology; PRISMA

Introduction

Background

A chronic condition of glucose metabolism known as "diabetes mellitus" is described by impaired insulin production and action. According to the etiopathology of diabetes, the 3 most common clinical classes are distinguished: type 1 diabetes (T1D), type 2 diabetes, and gestational diabetes mellitus [1,2]. T1D is the most common type of diabetes affecting children or adolescents, although it can occur in all age groups [3-6].

T1D is typically diagnosed at a young age. After a child is diagnosed with diabetes, the child and his caregiver or parents need a period of adaptation to the new situation. In addition, children or adolescents may struggle emotionally with their health conditions, especially those that are diagnosed early. Therefore, they need the support of their caregivers to manage their disease [6-8]. Caregivers are crucial supports for the ability of children or adolescents to self-manage T1D [6,7,9]. However, caregivers often report frustration, stress, and worry about their role [10]. This period after diagnosis can be challenging for both children and parents [8].

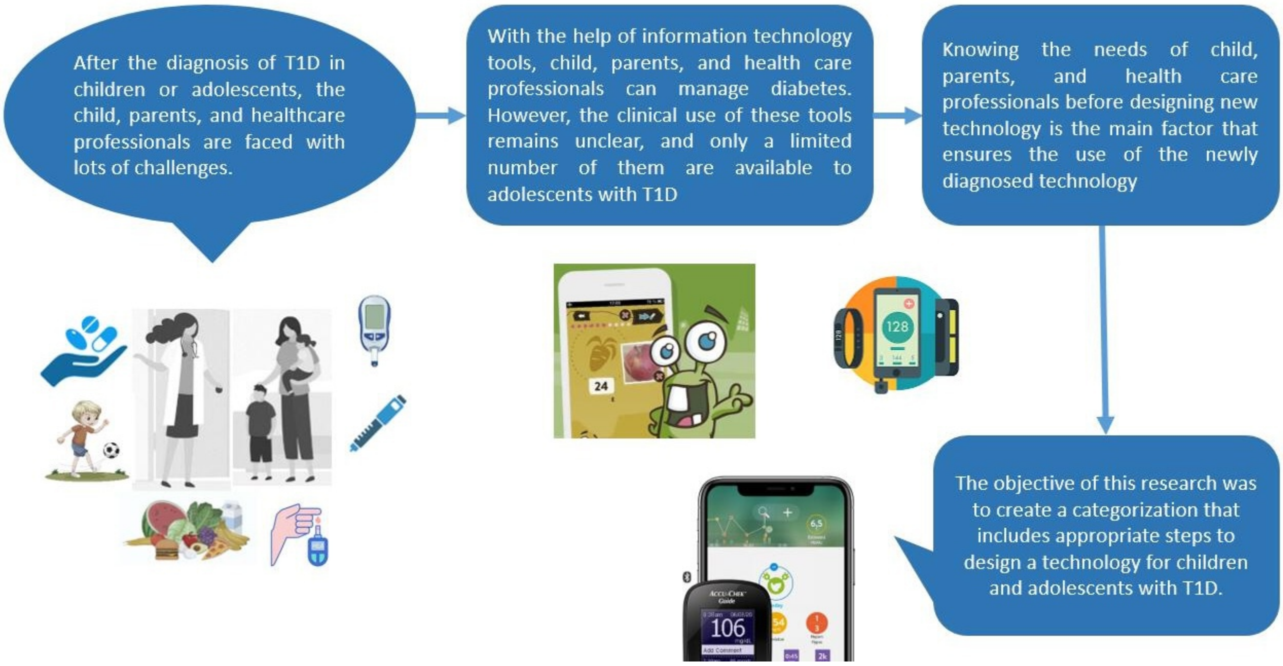
T1D requires a lifetime of self-management at home and in the community, which requires regular consultations with the health care team [11]. Intensive self-management is characterized by frequent self-monitoring of blood glucose (SMBG), physical activity, carbohydrate intake, and insulin doses by using multiple daily insulin injections or an insulin pump for basal and bolus insulin delivery [11,12]. Improved blood glucose control has been shown to reduce mortality and the incidence of serious and costly complications such as kidney and cardiovascular disease [11]. Achieving ideal blood glucose levels requires intensive self-management, which can be a challenge for young people [4]. Supporting adolescents and children in the self-management of T1D is an integral goal of health care. Health care professionals (HCPs) must guide insulin management and seek insight into the lived experiences of patients, such as social life, work, and school, to identify issues that influence self-management. In addition, adolescents or children with T1D often skip clinical visits, show a lack of adherence to monitor their hemoglobin A_{1C} (HbA_{1c}) trends, and endanger their current and future health [13-15].

The quality of services provided to patients with diabetes has increased due to advances in IT over the past few decades [16]. Numerous studies have investigated the efficiency of using websites, apps, and messaging systems as tools of IT to manage diabetes [4-7,13,17-23]. In this regard, along with various types of information technologies, the number of diabetes apps available for download on the iOS App Store and Google Play to improve diabetes self-management has proliferated recently [5,7,24]. The mobile health (mHealth) apps improve patient education and communication with HCPs and peers conveniently and interactively [13,25], especially among children or adolescents, an age group that easily adopts new technology [26].

Objective

This study aims to thoroughly catalog the variety of IT tools used in the management of diabetes among children or adolescents. The main goal is to identify the technologies that are most widely used by noting their frequency. The study also intends to investigate several approaches that are relevant to the creation of diabetes technology. It plans to provide developers in this industry with useful information by outlining the fundamental phases involved in the design process. Figure 1 shows the graphical abstract of the paper.

Figure 1. Graphical abstract. T1D: type 1 diabetes.



After the diagnosis of T1D in children or adolescents, the child, parents, and healthcare professionals are faced with lots of challenges.

With the help of information technology tools, child, parents, and health care professionals can manage diabetes. However, the clinical use of these tools remains unclear, and only a limited number of them are available to adolescents with T1D

Knowing the needs of child, parents, and health care professionals before designing new technology is the main factor that ensures the use of the newly diagnosed technology

The objective of this research was to create a categorization that includes appropriate steps to design a technology for children and adolescents with T1D.

Methods

The electronic databases used for the search were MEDLINE (PubMed), Web of Science, and Google Scholar. Keywords were “type 1 diabetes,” “adolescents,” “kids,” “mHealth,” “children,” and “coaching.” These were combined using the Boolean operator “AND” and included their respective synonyms with the operator “OR.” The inclusion criteria for the studies included open access, papers published in English from 2012 to 2023, patients with diabetes younger than 18 years, and consistent with the research goal. The criteria for exclusion were irrelevance to the major topic, older than 18 years, conference papers, reports, and theses. Our systematic database search identified 2080 studies from 3 databases. The study selection is using PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [27].

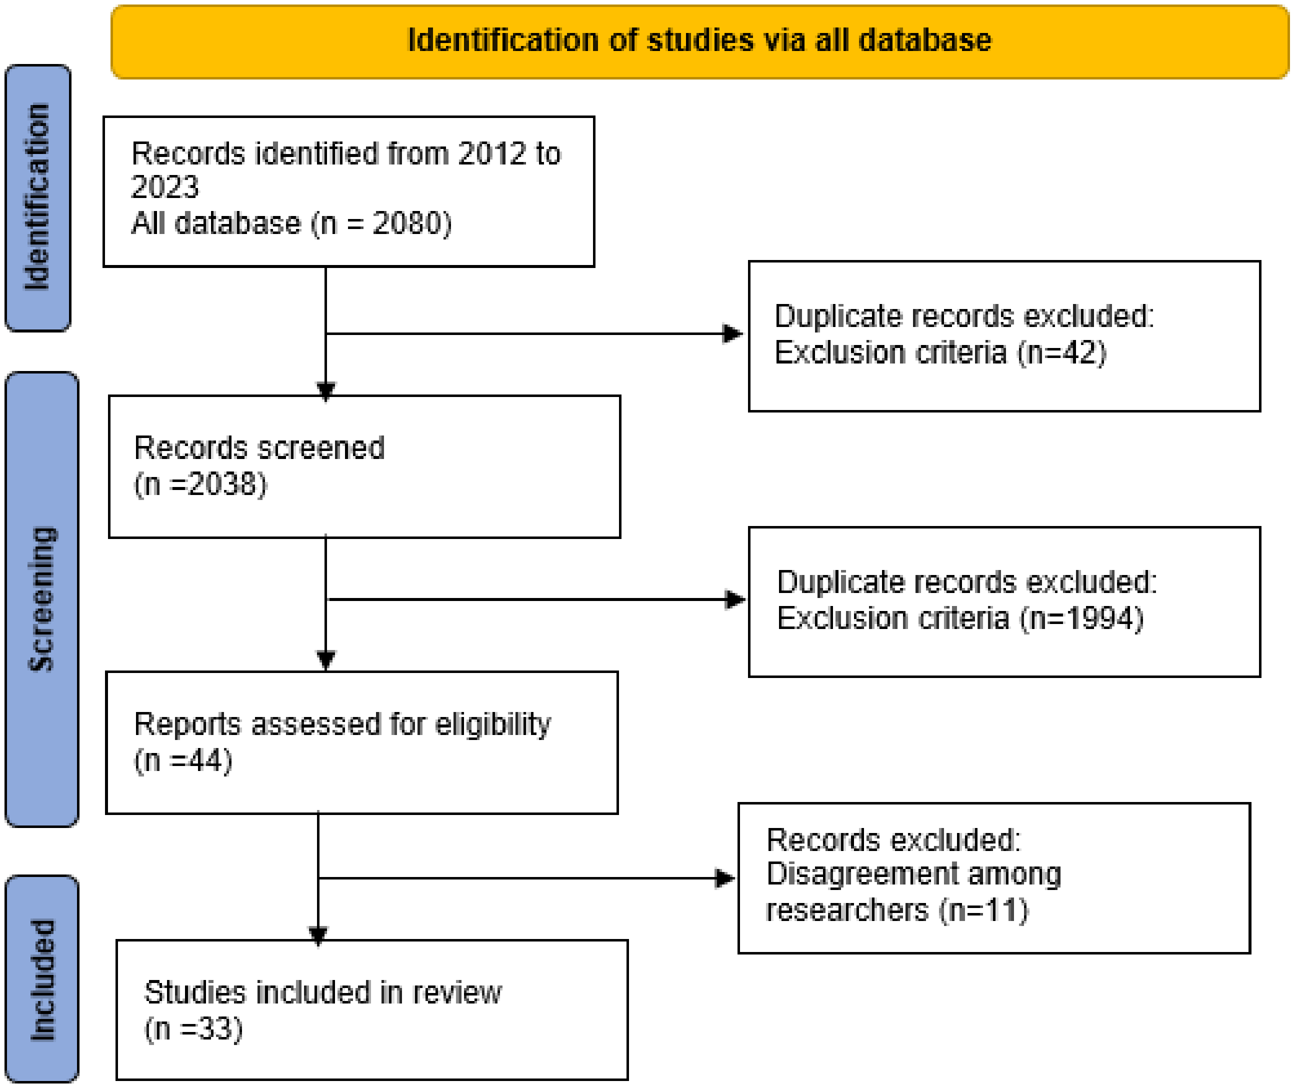
Results

Overview

Based on Figure 2, after filtering out publications based on duplication and exclusion criteria, only 44 remained. However, 11 of these were later excluded due to discrepancies among researchers. These papers did not achieve the consensus of researchers regarding their alignment with the objectives of the current research, leading to their exclusion. At the end of the selection process, 33 researchers fully agreed upon the papers. Of 33 research papers, 30 were in Google Scholar, 3 in PubMed, and nothing on Web of Science (after removing duplicates). Through exploration of the papers, it was initially found that the 3 main information technologies applied to the management of T1D among children or adolescents are the mHelath apps, the website, and the messaging system. Then, it became clear that the gamification, user-centered design (UCD), and text message systems were the 3 most popular methodologies to design new technology for diabetes. Finally, the procedures for creating a new technology for children or adolescents are as follows:

1. Types of IT
2. Methodological identification
3. Purpose identification
4. Feature determination

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.



Types of IT

Through reviewing the papers, it becomes apparent that there are 3 main types of IT that are used in the management of T1D among children or adolescents, which are shown in Table 1.

Table . Types of IT.

Platforms	References
mHealth[a]	[4,5,7,8,11-13,15-23,28-37]
Websites	[6,16,17,35,38,39]
Messaging system	[21,40,41]

[a] mHealth: mobile health.

Methodology Identification

Three methods were recognized for designing an IT for the management of T1D in children or adolescents, which are summarized in Table 2.

A comprehensive overview of various information technologies and their respective features has been compiled in Table S1 in Multimedia Appendix 1 to maintain the study's brevity and avoid unnecessary complexity resulting from an excess of tables.

Table . Methodology identification.

Methods	References
Gamification	[6,8,22,23,32,37,38]
Text message system	[21,40,41]
UCD[a]	[4,5,7,8,11-13,15-21,28-31,33-36,39]

[a] UCD: user-centered design.

Purpose Identification

Upon reading the papers, it was concluded that recognizing the goal is a significant step in the development of a new technology. Table 3 presents the categorization of the goals extracted from the papers.

Table . Purpose identification.

Goal	References
Self-monitor blood glucose value	[4,6-8,11,12,16,17,22,28,29,32,33,35,37,38]
Improve HbA$_{1c}$[a]	[5,7,12,20,29-31,36,40]
Self-manage insulin adjustment	[6,18,22,23,28,38]
Improve the life quality	[6-8,12,15,38]
Improve the communication among parents, adolescents or children, and HCPs[b]	[4,7,11,12,32]
Promote parents' knowledge about diabetes	[16,17,32-34,36,42]
Enhance adolescents' or children's knowledge about diabetes	[6,7,12,18,19,21-23,30,33,38,41]
Track physical activity	[6,35,38]
Track food intake	[6,18,21,30,38]
Develop a device-agnostic cloud platform to host diabetes device data	[39]

[a] HbA$_{1c}$: hemoglobin A$_{1c}$.

[b] HCPs: health care professionals.

Feature Determination

Identification of stakeholders is necessary before determining the characteristics of the technology. Identified stakeholders are parents, caregivers, HCPs, and children or adolescents with diabetes. In Table S1 in Multimedia Appendix 2, the lists of questions asked of stakeholders are attached. In the following, the summaries of the questions are mentioned.

Parents were often asked the following questions:

> *What information should be included in the app; Do you like to see trends in a child's blood glucose, HbA$_{1c}$, and fasting blood glucose; How do you manage an adolescent's diabetes; What challenges come with having children with diabetes; How much could a child with diabetes benefit from an application made specifically for this purpose.* [8,12,18,42]

Furthermore, the questions about designing technology with the intention of gamification were as follows:

> *What is the most appropriate game design for a child with diabetes (taking care of a character, quizzes, runner game, storytelling); What is the most appropriate reward style that should be used in the game; What features would you like to have in the game.* [37]

Furthermore, questions such as, "If your HbA_{1c} is below the target range, what kind of information or message would you like to receive from the app?"; "What types of goals would you like to be able to set for yourself?"; "What was your experience and feelings about being diagnosed with diabetes?"; and "How do you deal with diabetes?" were frequently asked of adolescents [12,19]. Furthermore, "What thoughts and wishes are there regarding a virtual platform for children/adolescents?" [23]; this is a kind of question that was asked of HCPs.

Through the analysis of the responses of stakeholders to the questions, technological features emerge. Concise summaries of the features of the diabetes app are shown in Table 4.

Table . Feature determination.

Features	References

Review of Current Technologies

Another point to consider when designing new technology is how successful the previously introduced technologies have been in achieving their goals. For the treatment of T1D in adolescents, Cafazzo et al [11] designed the Bant app using gamification incentives. They showed that the app improves the frequency of blood glucose monitoring in adolescents. Alsalman et al [23] proposed a gamification app in 2021; however, they have not provided any evidence of the app's usefulness. In addition, Schmidt et al [22] created the gamification app in 2022, but they have not yet shared any user evaluation data. In 2017, den Akker et al [38] described a platform, PERMAGON, that integrates gaming and coaching for adolescents with type I diabetes. The purpose of the platform was to support patients and their caregivers in self-management of diabetes through educational games, monitoring, and motivational feedback. In 2018, Klaassen et al [6] conducted a study to evaluate the efficacy of PERGAMON. They asked participants: "Do you expect that the PERGAMON platform will support you in your diabetes management?" Approximately 33.33% (33/100) of the participants answered "yes," which proved the effectiveness of the platform.

In 2017, Goyal et al [4] conducted a study on the Bant app to determine its impacts on HbA_{1c} and SMBG. They showed that the app has a positive impact on the use of SMBG data and glycemic control among youth. Klee et al [5] demonstrated that the Webdia app reduced HbA_{1c} levels in children who used it without increasing their prevalence of hypoglycemia. In 2017, Holtz et al [12] designed the MyT1DHero app using patient-centered methods to recognize their requirements. The participants confirmed that the new app would improve communication between parents and adolescents. The effectiveness of the MyT1DHero app in enhancing HbA_{1c} levels, adherence to diabetes care adherence, and quality of life was investigated in a new study by Holtz et al [7] in 2021. They showed that the app facilitates parent-adolescent communication, adherence to self-care, and improvement in quality of life. An Arabic-language application called Ana Alsukary was created in Saudi Arabia by Bitar et al [8]. This app consists of several features, one of which the users were interested in, namely, showing the location of stores that offer diabetes-friendly products. Caregivers of children with diabetes indicated that the app helps children understand their diabetes and adjust their lifestyle accordingly.

In 2017, Castensøe-Seidenfaden et al [13] designed a new app, Young with Diabetes (YWD), to support young people in the self-management of T1D. In 2018, Husted et al [15] examined the influence of YWD on young people's self-management for 12 months. Participants mentioned that peer support reduced feelings of loneliness and helped them acquire knowledge and skills to manage T1D. Another study was carried out by Castensøe-Seidenfaden et al. in 2018 [20] to investigate the effectiveness of YWD in improving HbA_{1c} levels. The results demonstrated that the value of the app could not improve HbA_{1c} but could be a useful addition to self-management. In another study by Ledderer et al [28], adolescents using the Diapplo app appreciated the design and user interface of the app as well as the functions to have an overview of blood glucose values. However, they stated that the content of the app only partially met their needs. They suggested integrating social networks into the app and providing more knowledge on how to deal with chronic diseases. Albanese-O'Neill et al [17] created an online DSMES website and a separate mobile subdomain for fathers, Mobile Diabetes Advice for Dads (mDAD). They evaluated a prototype of the site with fathers' participants. Information on mDAD was believed to be helpful by 55% (55/100) of fathers. Since many young adults with T1D struggle with the complex daily demands of adherence to their medical regimen and do not achieve glycemic control in the target range glycemic control, Stanger et al [36] provided a mobile app, SweetGoals, to study its ability to help young adults comply with their medical regimen. The results of their experiment will be published by December 2025.

Berndt et al [16] investigated the impact of Mobile Diab, a new mobile, website, and communication technology, to help the treatment and treatment of adolescents with T1D. They observed an improvement in the mean HbA_{1c} level. Frøisland et al [21] compared 2 types of technology, the Diamob application and diabetes message system, to determine which could have a better impact on diabetes management than others. The objectives of the Diamob app were communication between the patient and the health care team about carbohydrate consumption, insulin dosage, and types of physical activity. The diabetes message system has been used to send educational messages to patients and messages to HCPs when faced with obstacles in daily life. As a result, adolescents found both the Diamob and the diabetes message system practical as support for their diabetes self-management. They appreciated Diamob more than the text message app. In 2015, Frøisland and Årsand [30] developed and tested a new feature for Diamob that allowed one to take pictures of the food and then measure the carbohydrates in the food, the insulin dose needed, and the type and amount of physical activity. They concluded that adding this feature would go a long way toward helping young people understand the basics of diabetes. Hilliard et al [34] created and tested a new mHealth app for parents of teens with T1D, which is Type 1 Doing Well. Parents claimed that the app had high acceptance and the greatest suitability for providing information. The CanDIT (Canadian Diabetes Incentives and Technology) app was developed by Krmpotic et al [29]. The app was evaluated by a small number of youths. They stated that they use the app most often for SMBG. They reported that they liked the ability to set reminders and view their glucose history. They listed several suggestions for improving the app, such as the ability to personalize target blood glucose ranges, calculate insulin doses, enter blood glucose values, and track carbohydrate intake. Shetty et al [31] claimed that enabling young people with T1D to control their blood glucose levels during exercise is a complex challenge for HCPs. Therefore, they asked 10 young people with T1D to use the acT1ve mHealth app to help them exercise in real time. Participants indicated that the app improved their knowledge and boosted their confidence when exercising.

Zholdas et al [35] presented an information on technology–based mHealth monitoring system, including sensors, medical bracelets, and mobile devices with applications to calculate the probable change in a patient's blood glucose level after the end of physical activity. After a test, they demonstrated a drop in blood glucose levels after physical activity, which confirms their hypothesis that there is a link between physical activity and blood glucose levels. To host data from diabetic devices and develop an ecosystem of software innovation to treat T1D care, Neinstein et al [39] created a device-agnostic cloud platform, Tidepool, to host data from diabetic devices and catalyze an ecosystem of software innovation for T1D management. They concluded that the Tidepool platform can solve 2 current problems in the T1D device landscape: limited access to T1D device data and poor interoperability of data from different devices.

Text messaging is another type of platform used by researchers. Bin-Abbas et al [40] conducted a mobile phone messaging service for children or adolescents with T1D. Three types of mobile phone messages have been sent to children through their parents, including informational messages, interactive messages, and multimedia messages. The results showed that HbA_{1c} levels were significantly reduced, parents' knowledge of diabetes improved significantly, and text messages on mobile phones were a useful way of contacting each other between clinic visits. Zhang et al [41] conducted another study with the hypothesis that higher levels of participation in the intervention would yield better diabetes management and examined whether caregiver participation or other demographic factors were associated with the level of participation. They concluded that there was a good level of participation in a text messaging intervention for adolescents with T1D, and high participation was related to a greater improvement in caregiver-reported adherence. Race, ethnicity, and sex were the only demographic factors significantly related to the level of participation.

Discussion

Principal Findings

Management of diabetes can be difficult for children or adolescents, parents, and HCPs. To address this, technology plays a vital role in providing support. These modern technologies are characterized by significantly better cost-effectiveness, which is a stark contrast to traditional, more expensive alternatives. Unlike traditional systems, they eliminate typical total cost of ownership issues [43]. To better assist adolescents or children dealing with T1D, this study conducted a comprehensive assessment aimed at initially cataloging the range of IT tools used in diabetes management and pinpointing the most prevalent technologies used. Furthermore, the study delved into various methodologies relevant to the development of diabetes technology. Finally, it aims to provide developers in this field with valuable insights by delineating the fundamental phases inherent in the design process. Through a review of the literature, it became apparent that there are 4 key steps involved in designing a novel technology for the management of diabetes.

The initial step, as previously discussed, entails identifying the predominant IT used. In this regard, the mHealth apps emerged as the leader with 27 mentions, followed by websites with 5 mentions and text message systems with 3 mentions. This high frequency of mHealth apps is because children or adolescents have easy access to mobile phones, encouraging technology innovators to create more mHealth apps specifically for the management of diabetes. This finding corroborates previous research [13,25] indicating that mHealth apps effectively enhance patient education and communication with HCPs and children or adolescents conveniently and interactively.

The second step was to identify the main methodology for designing a new technology for children or adolescents with diabetes. It was evident that the most popular methodology is UCD, with 22 mentions. Gamification was referenced 8 times after UCD and messaging systems were cited 3 times. Gamification is the application of concepts of game design to the creation of settings that can encourage individuals to make healthier decisions [37]. Text message system is technique that uses a mobile phone to send messages to patients and their parents. UCD involved designing the app with the end user in mind, focusing on their needs, preferences, and behaviors throughout the design process. The age range of children or adolescents indicates that gamification may be the most successful strategy to motivate patients with diabetes to actively interact with the program, although UCD emerged as the most popular methodology. This can greatly support their attempts at self-management and encourage regular use, which will improve the management of their diabetes. Visualization plays a key role in captivating the interest of children and adolescents, making gamification an ideal avenue to incorporate various visually stimulating features. By creating a vibrant virtual world replete with colorful imagery, captivating stories, and charming characters, gamification provides the necessary motivation for patients with diabetes to use the app regularly. Through this engaging approach, the primary objective of helping patients manage their condition can be achieved in a lighthearted and enjoyable manner, particularly appealing to the younger demographic.

The third step involved identifying the core objectives that underlie the development of a new technology. Upon careful review of the literature, it became evident that SMBG values emerged as the primary purpose, cited 20 times. Following closely, the secondary objective was to improve HbA_{1c} levels, as mentioned 12 times. Finally, the objective of improving overall quality of life and increasing adolescents and children's knowledge about diabetes was highlighted 9 times. Among other goals, the frequency of SMBG highlights how crucial it is to build new technologies with the primary goal of helping patients monitor their blood glucose levels effectively. It is imperative to give priority to features that optimize blood glucose monitoring since they help patients reduce the risk of hypoglycemia and other related problems, improving their overall health.

The final step in technology design involves careful consideration of its features. Upon review, it became evident that patient education ranked highest with 23 mentions, followed closely by carbohydrate counting with 22 mentions and blood glucose tracking with 21 mentions. This underscores the importance of incorporating these key features into the design of a technology. It is clear that for children and adolescents, independent learning can be challenging, emphasizing the necessity of providing intuitive icons to support patients and caregivers in managing diabetes effectively. In addition, accurate carbohydrate counting is paramount, as any miscalculation can lead to incorrect insulin dosing, posing significant risks to the patient's well-being.

Based on our findings, we recommend that developers prioritize the creation of an mHealth app using a gamification methodology to design new diabetes management technologies. This approach should encompass essential characteristics such as blood glucose management, suggestions for improving HbA_{1c}, carbohydrate counting, and comprehensive educational resources for both patients and caregivers. By emphasizing these aspects, developers can ensure the effectiveness and user-friendliness of the technology, ultimately enhancing its use in supporting children or adolescents with diabetes in their daily management routines.

Limitations

The primary challenges encountered during this review stemmed from variations in the number of articles reviewed compared with the technologies identified. For instance, each group of papers (eg, [4,11], [7,12], [6,38], [21,30], and [13,15,20]) referenced a unique single app. In addition, article [8] mentioned 5 distinct apps; article [17] cited 2 separate apps; and article [37] included 3 apps, which add further complexity to the analysis. These differences make reviewing and analyzing the results more difficult and time-consuming.

Acknowledgments

This research was supported by the project TN02000067—Future Electronics for Industry 4.0 and Medical 4.0 cofinanced from the state budget by the Czech Republic Technology Agency under the National Centers of Competence: Support Program for applied research, experimental development, and innovation. All authors have read and approved the final manuscript.

Abstract

Background: Premature birth rates have slightly increased globally, making its prevention critical for both short-term and long-term health outcomes. Various interventions have been developed in response to the multifaceted risk factors for premature birth, including internet-based programs. These programs offer accessibility and enhanced engagement; however, their overall efficacy in preventing premature births requires thorough evaluation.

Objective: This systematic review aims to identify the study designs and assess the effectiveness of internet-based interventions in preventing premature birth among pregnant women.

Methods: A comprehensive search of the MEDLINE, Embase, CINAHL, and Cochrane Library databases was conducted to identify randomized trials and quasi-experimental studies evaluating internet-based interventions for premature birth prevention in pregnant women. The search was inclusive, with no restrictions based on language or geographical location, allowing for a comprehensive global perspective. The time frame for the inclusion of studies extended until February 2023. The risk of bias (RoB) in each study was independently assessed by 3 authors forming pairs, using the revised Cochrane RoB tool (RoB 2) for randomized trials, as per the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. Owing to heterogeneity in populations, measurements, and interventions, a meta-analysis was not conducted.

Results: This review included 26 articles, comprising 12 intention-to-treat and 14 per-protocol studies. The overall RoB was high in most intention-to-treat studies and of some concern in most per-protocol studies. The target populations varied, including nonspecific pregnant women, those with gestational diabetes mellitus (GDM) or those at risk of GDM, individuals with anxiety or depression, and those experiencing preterm labor. Psychosocial, physiological, and wellness health outcomes were evaluated. Internet-based interventions effectively reduced stress/distress in nonspecific pregnant women but not in those experiencing preterm labor. Their effectiveness in reducing anxiety and depression varied, with inconsistent results among different groups. In women with GDM or those at risk of GDM, interventions successfully controlled fasting plasma glucose and 2-hour postprandial plasma glucose levels but did not consistently manage glycated hemoglobin levels. These interventions did not reduce the incidence of premature births across the various populations studied. The effectiveness of these internet-based interventions in addressing substance or alcohol abuse and insomnia also varied.

Conclusions: Internet-based interventions show promise in improving psychosocial health and managing blood sugar to prevent premature birth, highlighting variability in effectiveness across different risk factors. Further research, including clinical trials, is vital for developing, evaluating, and disseminating effective, safe internet-based interventions. Establishing standardized measurement tools and rigorous evaluation processes is crucial for enhancing these interventions' effectiveness and reliability in clinical practice, significantly contributing to preventing premature births and improving maternal health outcomes.

Introduction

Background

The estimated global premature birth rate per 100 live births increased slightly from 9.8% (13.8 million premature births) in 2010 to 9.9% (13.4 million premature births) in 2020 [1]. This indicates an average annual increase rate in premature birth prevalence of 0.14% [1]. Complications of premature birth are the leading cause of childhood mortality, which refers to the probability of dying between birth and exactly 5 years of age, expressed per 1000 live births. This encompasses 35% of neonatal deaths and 18% of deaths in children aged <5 years [2]. Compared with their term-born peers, premature babies are more likely to develop respiratory distress syndrome, sleep apnea, necrotizing enterocolitis, and intraventricular hemorrhage in the neonatal period [3] and have worse cognitive, language, and motor development and social-emotional competence as children aged <5 years [4,5]. In addition, young adults born preterm are more susceptible to psychological fragility (in terms of anxiety and insecurity) and tend to exhibit lower cognitive ability [6]. Therefore, reducing the incidence of premature births is of utmost importance for the short- and long-term health and development of children.

Sociodemographic, nutritional, medical, obstetric, and environmental factors can increase the risk of premature birth. Consequently, interventions have been developed to prevent or mitigate known modifiable risk factors for premature birth [7]. Primary and secondary prevention encompasses a wide range of interventions, including medication, surgical procedures, cervical devices, targeted diets, physical exercise, smoking cessation programs, nutritional supplementation, education, and various special tests or investigations [7,8]. For women to participate in preventive activities for primary health promotion; secondary activities; and tertiary activities, including lifestyle modification, health screening uptake, treatment compliance, and participation in rehabilitation programs, understanding and continuous motivation are required. Recently, internet-based interventions have been developed to provide health-related information to individuals who may not have direct access to medical facilities [9], offering accessibility and availability regardless of time and location [10]. In addition, internet-based interventions can enhance engagement with self-monitoring, promote health-related understanding, and increase knowledge and risk perception of disease as well as bolster self-efficacy in disease management [11].

Previous systematic reviews have thoroughly examined interventions aimed at preventing premature birth, evaluating the overall evidence for such interventions [7,8,12,13]. These reviews covered a range of specific interventions, including infection treatment [14], pharmacological methods [15-17], nutrient supplementation [18], cerclage [19], cervical devices [20], and social support [21]. However, to date, only 2 systematic reviews have explored internet-based interventions in this context, confirming the effectiveness of technology-supported lifestyle interventions [22] and telemedicine [23] specifically for pregnant women with gestational diabetes mellitus (GDM). Although the effectiveness of internet-based interventions for smoking cessation among pregnant women [24] and prenatal interventions for maternal health [25] has been established, their effectiveness in preventing premature birth remains unconfirmed.

Objectives

To address this gap, we conducted a systematic review of randomized controlled trials (RCTs) and quasi-experimental studies focusing on internet-based interventions for premature birth prevention. The objectives of this review were three-fold: (1) to describe the general characteristics of the studies included, (2) to identify the study designs of internet-based interventions pertinent to premature birth prevention, and (3) to evaluate the effectiveness of internet-based interventions in achieving outcomes related to premature birth prevention among the target population.

Methods

Design

This systematic review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [26] and registered in PROSPERO (CRD42021278847). Our review focused on 2 specific research questions formulated using the Population, Intervention, Comparison, and Outcome strategy: (1) What is the efficacy of internet-based interventions in reducing the risk of premature birth among pregnant women compared to standard prenatal care? (2) How do internet-based interventions impact maternal health outcomes, such as stress, anxiety, and gestational diabetes, in pregnant women at risk of premature birth? These questions aimed to evaluate the effectiveness of internet-based interventions in both reducing premature births and improving crucial maternal health outcomes. Our systematic search targeted several electronic databases, including MEDLINE, Embase, CINAHL, and the Cochrane Library, focusing on studies published up to February 2023. To augment our database search, we manually reviewed the reference lists of the included publications.

Eligibility Criteria

Our inclusion criteria encompassed published RCTs, quasi-experimental studies, and experimental studies on the prevention of premature birth. We imposed no restrictions regarding the country or language of publication. The target population included all pregnant women, including those with normal or high-risk pregnancies, pregnancy complications, or at risk of premature birth. The interventions were internet-based and used various devices, such as computers and mobile phones. We excluded cross-sectional, case-control, retrospective, and prospective cohort studies; noncomparator experimental studies; animal experiments; reviews; qualitative studies; case reports; unpublished data; and gray literature, such as conference abstracts, letters, editorials, dissertations, and unavailable full texts. Studies targeting prepregnant women, women in the postpartum period, women outside childbearing age, and men were also excluded.

Search Strategy

Adapted search terms for each database included a combination of terms related to population (eg, “women”), pregnancy (eg, “premature birth” and “pregnancy”), information and communication technology (eg, “computer”), treatment (eg, “internet” and “online”), and study design (eg, “randomized controlled trial”). These terms were used to search titles, abstracts, keywords, or text words. The exact search terms are detailed in Multimedia Appendix 1.

Selection and Data Collection Processes

All identified studies were first imported into a reference manager for deduplication. The titles and abstracts were then independently screened by 2 of the 3 reviewers, working in rotating pairs (ie, A and B, B and C, and A and C). Following this initial screening, relevant studies underwent a full-text review. Disagreements at this stage were resolved through discussion or consultation with the third reviewer, ensuring a consensus on the inclusion of studies. Any studies found to be irrelevant after full-text review were excluded from further consideration. Simultaneously, a data extraction form was collaboratively developed and pretested by the reviewers to systematically collect review characteristics and outcome data from the selected studies. This process of data extraction was also conducted independently by 2 pairs of reviewers. In cases of discrepancies in the extracted data, the reviewers engaged in discussions to reach a consensus or consulted the third reviewer for an objective resolution.

Data Extraction

The extracted data included study characteristics (eg, authors, year, country of origin, research design, and sample size), study results (primary and secondary findings for outcome measures, including effect sizes), and intervention details (eg, name, method, timing, duration, and group type). Because of the variation in methodologies across studies, conducting a meta-analysis was considered unsuitable. Instead, information was synthesized narratively, categorizing outcomes into psychosocial, physiological, and wellness health outcomes. Effect sizes were calculated using means and SDs or frequencies and percentages depending on the study design.

RoB Assessment

Two pairs of reviewers independently assessed the methodological quality using the revised Cochrane RoB tool for randomized trials [27]. This tool evaluates 5 domains: randomization process, deviation from intended interventions, missing outcome data, outcome measurement, and reported result selection grouped into 3 levels of RoB (low risk, some concern, and high risk). Studies were categorized into 2 groups: intention-to-treat (ITT) and per-protocol (PP), with disagreements resolved through discussion or consultation with a third person.

Statistical Analysis

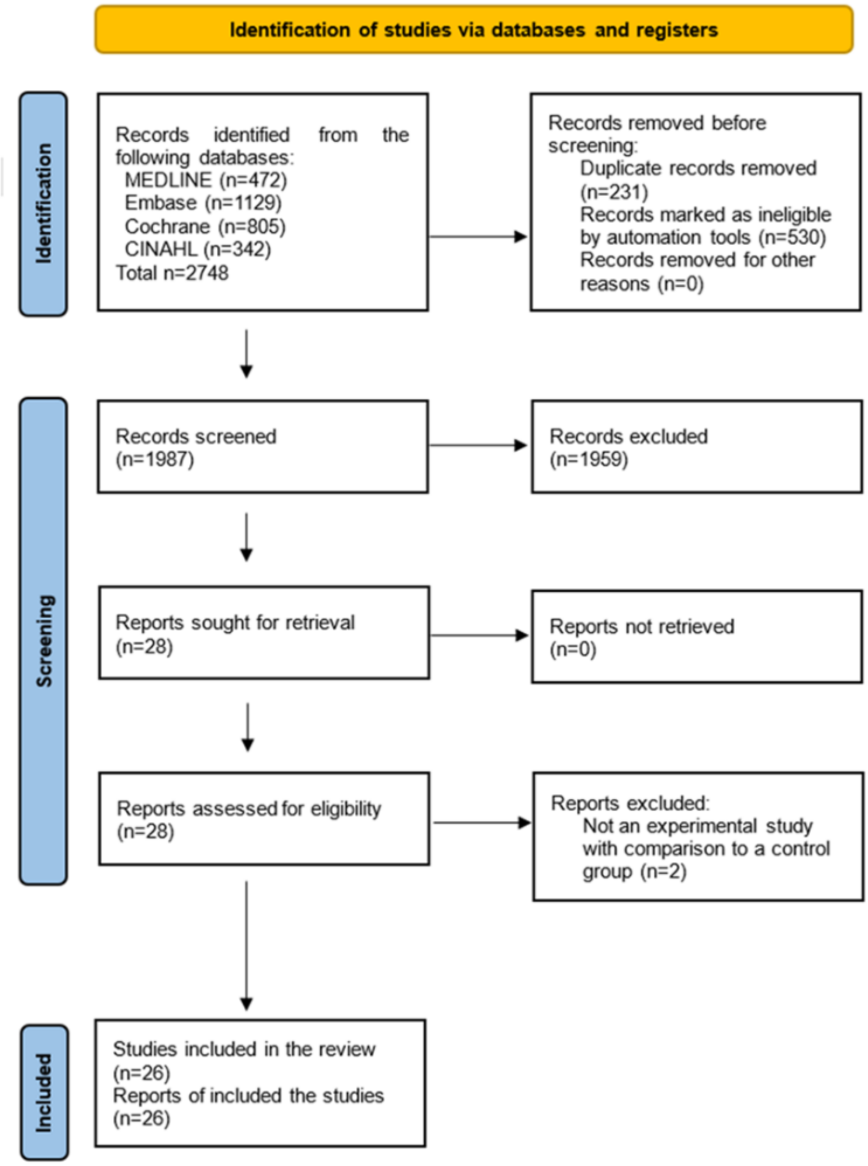
Owing to the heterogeneity in interventions and participant characteristics, we opted for a narrative synthesis instead of a meta-analysis. When available, effect sizes were calculated using data from the studies, using various metrics such as Cohen *d*, Cohen *f*, Morris *d*, Hedges *g*, Cohen *h*, odds ratio (*P* value and 95% CI), and relative risk (95% CI and *P* value) [28]. Of the 26 papers reviewed, 5 (19%) lacked sufficient statistical data to calculate the effect size of the intervention. We reached out to the authors of these papers for additional information. However, responses were not received for several of these inquiries, limiting our ability to calculate effect sizes for all studies. Consequently, effect sizes were calculated for 21 articles. In instances where additional data from the original authors were not obtained, our evaluations were based on the information available in the study. In cases where studies presented results solely in graphical form, we calculated effect sizes where possible, specifically if the graph provided measurable mean and SD. However, for graphics lacking detailed data, such as missing SDs, effect size calculation was not feasible.

Results

Overview

Initially, a total of 2748 articles were retrieved from the 4 databases. After excluding 761 duplicate articles, 1987 remained. During the initial screening stage, 1959 papers were excluded after reviewing the study title and abstract. The full texts of the remaining 28 studies were reviewed, and 2 studies that were not controlled comparative experimental studies—they were 1-group pre- and postintervention comparison studies—were excluded. Finally, 26 studies were selected for the systematic review. Figure 1 illustrates the study selection process.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram showing the selection of included studies.



Quality of the Studies and RoB Assessment

In the subset of studies that used ITT analysis, the overall RoB was categorized as low for 17% (2/12) of the studies, exhibiting some concerns in 25% (3/12) of the studies, and high in 58% (7/12) of the studies. Among the studies using PP analysis, only 7% (1/14) of the studies were assessed as having a low RoB, whereas 57% (8/14) of the studies had some concerns, and 36% (5/14) of the studies were deemed to have a high risk. The detailed outcomes of the RoB assessment for the 12 ITT and 14 PP studies are shown in Figure 2.

Figure 2. Risk-of-bias (RoB) assessment using the revised Cochrane RoB tool for randomized trials [29-54].

Study Characteristics

The 26 studies included in this review were conducted across various countries, with the largest number from the United States (6/26, 23% studies [29-34]), followed by China (4/26, 15% studies [35-38]), Taiwan (3/26, 11% studies [39-41]), Switzerland (2/26, 8% studies [42,43]), and the United Kingdom (2/26, 8% studies [44,45]). In addition, 1 study each was conducted in Australia [46], Canada [47], Iran [48], Ireland [49], the Netherlands [50], Norway [51], Spain [52], Sweden [53], and Thailand [54]. The publication years spanned from 1996 to 2022, with most studies (14/26, 54%) [32-34,40-46,49,51-53] published between 2010 and 2019, 42% (11/26) of the studies [29,31,35-39,47,48,50,54] published from 2020 to the time of the review, and 4% (1/26) of the studies [30] published before 2000. Among these, one study was published in Chinese [35] and another in Persian [48], with the remaining studies all written in English.

With regard to research design, 81% (21/26) of the studies used a randomized controlled experimental design [30-39,42-46,49-54], whereas 19% (5/26) of the studies used a quasi-experimental design [29,40,41,47,48]. The focus of these studies varied, with 8% (2/26) of the studies targeting pregnant women diagnosed with anxiety or depression [46,53], 27% (7/26) focusing on pregnant women with GDM or at risk of GDM [29,35,37-39,47,52], and 8% (2/26) involving women experiencing preterm labor [42,43]. Of the 26 studies, 1 (4%) was dedicated to pregnant smokers [44], 2 (8%) were dedicated to pregnant women using drugs or alcohol [30,34], and 1 (4%) was dedicated to those experiencing insomnia [31]. The remaining 42% (11/26) of the studies targeted nonspecific pregnant populations [32,33,36,40,41,45,48-51,54]. Detailed information on these studies is provided in Tables 1 and 2.

Table 2. Summary of the study designs for internet-based interventions in pregnant women (N=26).

Study, year; country	Study design (analysis sets)	Participants (intervention n/control n)	Experimental intervention	Intervention method and group type (I[a] or G[b])	Intervention timing and duration	Comparative intervention
Alemi et al [30], 1996; United States	2-armed RCT[c] (PP[d])	Pregnant drug-using participants from the previous study (28/25)	Talknet: a voice bulletin board for electronic self-help and group support	Communication via electronic bulletin boards: touch tone telephone (G)	Third trimester, intrapartum and 4 months	None
Chen et al [36], 2020; China	2-armed RCT (PP)	Pregnant women (83/85)	Health education on enhancing the compliance	Instant messenger by mobile phone	First, second, and third trimester and NR[e] (≥3 web-based courses)	Usual antenatal health education
Felder et al [31], 2020; United States	2-armed RCT (ITT[f])	<28 weeks' gestation with insomnia (105/103)	Sleepio (Big Health), digital cognitive behavioral therapy for insomnia	Website or mobile app (I)	First, second, and early third trimester (≤GA[g] 32 wks) and 6 wks	Usual treatment
Forsell et al [53], 2017; Sweden	2-armed RCT (PP)	10-28 weeks' gestation with depression (22/20)	ICBT[h] for antenatal depression	Website (I)	Late first, second, and third trimester and 10 wks	None
Goudarzi et al [48], 2021; Iran	2-armed quasi-experimental trial (PP)	<24 weeks' gestation (12/13)	Web-based unified transdiagnostic treatment on mental health problems	Instant messenger by mobile phone (G)	First, second, and early third trimester and 8 wks	NR
Guo et al [37], 2021; China	2-armed RCT (PP)	24-28 weeks' gestation; first-diagnosed GDM[i] (70/70)	Online-offline integrated medical care management	Offline and instant messenger by mobile phone (I)	Late second and third trimester and approximately 24-28 wks	None
Haga et al [51], 2019; Norway	2-armed RCT (ITT)	21-25 weeks' gestation (678/664)	Mamma Mia: a universal preventive intervention for perinatal depressive symptoms	Website (I)	Second and third trimester as well as post partum and 11.5 mo	Usual perinatal care
Heller et al [50], 2020; The Netherlands	2-armed RCT (ITT and PP)	<30 weeks' gestation (79/80)	MamaKits Online (internet-based problem-solving treatment) of depression and anxiety in pregnancy	Website (I)	First, second, and third trimester and 5 wks	None
Herbec et al [44], 2014; United Kingdom	2-armed RCT (ITT)	Pregnant smoking women (99/101)	MumsQuit: internet-based smoking cessation	Internet-based, access face-to-face, or telephone support (I)	First, second, and third trimester and 4 wks of prequit date support and up to 4 weeks of postquit date support (8 weeks)	One-page static, nonpersonalized website that provided brief standard advice
Huang et al [35], 2021; China	2-armed RCT (PP)	Pregnant women with GDM (144/151)	Mobile health management on GDM	Instant messenger by mobile phone (G)	Late second and third trimester and approximately 12-20 wks	Usual prenatal care
Krusche et al [45], 2018; United Kingdom	2-armed RCT (ITT)	12-34 weeks' gestation (107/78)	Be Mindful online	Website (I)	Late first, second, and third trimester and 4 wks	None
Lemelin et al [47], 2020; Canada	2-armed quasi-experimental trial (ITT)	21-30 weeks' gestation with newly diagnosed GDM (80/81)	Telehomecare (THCa) program for GDM management	Website (I)	Late second and third trimester and approximately 10-20 wks (until delivery)	None
Loughnan et al [46], 2019; Australia	2-armed RCT (ITT)	13-30 weeks' gestation with anxiety or depression (18/33)	MUMentum (unguided ICBT) for antenatal anxiety and depression	Website (I)	Second and third trimester and 4 wks	Usual treatment

Study, year; country	Study design (analysis sets)	Participants (intervention n/control n)	Experimental intervention	Intervention method and group type (I[a] or G[b])	Intervention timing and duration	Comparative intervention
Lu and Huang [38], 2022; China	2-armed RCT (PP)	Pregnant women with GDM (44/44)	Fetal monitoring using Internet of Things and GDM educational information	Instant messenger by mobile phone (I)	Late second and third trimester and 3 mo	Usual prenatal care
Matvienko-Sikar and Dockray [49], 2017; Ireland	3-armed RCT; 2-armed RCT for analysis (PP)	10-22 weeks' gestation (24/12)	Online mindfulness and gratitude intervention (body scan and reflection intervention)	Websites (I)	Second trimester and 3 wks	Usual treatment
Olson et al [32], 2018; United States	2-armed RCT (ITT and PP)	≤20 weeks' gestation (1126/563)	e-Mom, m-Mom: self-help, integrated mobile phone and web-based behavior change intervention in preventing excessive gestational weight gain	Website (I)	Late first, second, and third trimester and 28-30 wks	None
Perez-Ferre et al [52], 2010; Spain	2-armed RCT (PP)	24-28 weeks' gestation with GDM (49/48)	Telemedicine system	Telemedicine system based on internet and SMS text messaging (I)	Late second and third trimester and approximately 16-18 wks	None
Scherer et al [43], 2016; Switzerland	2-armed RCT (PP)	18-32 weeks' gestation with preterm labor (31/27)	Internet-based cognitive behavioral stress management	Website (I)	Late second and third trimester an 6 wks	None
Smith et al [33], 2016; United States	2-armed RCT (PP)	10-14 weeks' gestation (24/21)	Web-based behavioral intervention preventing excessive gestational weight gain	Website (I)	Late first, second, and third trimester, (3 weeks during GA approximately 10-36 wks) and approximately 20-26 wks	None
Su et al [39], 2021; Taiwan	2-armed RCT (ITT)	Pregnant women with GDM risk factors (56/56)	Web-based health management in preventing women at high risk of GDM from developing metabolic syndrome	Website, instant messenger by mobile phone (I)	Late second and third trimester as well as approximately 6-12 wks post partum and 6 mo	Usual prenatal care
Tomyabatra [54], 2020; Thailand	2-armed RCT (ITT)	Pregnant women (602/558)	Antenatal health education using audio-video social network about severe obstetric symptoms	Instant messenger: LINE app by mobile phone (G)	First, second, and third trimester and approximately 30-36 wks	Usual antenatal health education
Tsai et al [40], 2018; Taiwan	2-armed quasi-experimental trial (PP)	16-24 weeks' gestation (68/67)	Web-based antenatal care system and routine antenatal education	Website (I)	Second and third trimester and approximately 12-22 wks	Usual antenatal health education
Tzilos Wernette et al [34], 2018; United States	2-armed RCT (PP)	Unplanned pregnant women, condomless sex, and alcohol or drug use or at risk for prenatal alcohol/drug use (31/19)	Health Checkup for Expectant Moms of substance use and risky sex	Computerizing intervention authoring system (I)	First, second and third trimester and approximately 75 min	Watching brief segments of popular television shows with subsequent questions
Urech et al [42], 2017; Switzerland	2-armed RCT (PP)	18-32 weeks' gestation diagnosed preterm labor (50/43)	Internet-based cognitive behavioral stress management	Website (I)	Late second and third trimester and 6 wks	None
Whitcombe et al [29], 2021; United States	3-armed quasi-experimental trial (ITT)	21-30 weeks' gestation with newly diagnosed GDM (21/45/37)	Web-Based Instruction on Nutrition	Website (I)	Late second and third trimester and NR	None

Study, year; country	Study design (analysis sets)	Participants (intervention n/control n)	Experimental intervention	Intervention method and group type (I[a] or G[b])	Intervention timing and duration	Comparative intervention
Wu and Hung [41], 2019; Taiwan	2-armed quasi-experimental trial (ITT)	<12 week's gestation (66/55)	The Expectant Mother Club: Virtual Community	Closed social network community: closed community (G)	First, second, and third trimester and at least 24-26 wks	Usual prenatal care

[a] I: individual.

[b] G: group.

[c] RCT: randomized controlled trial.

[d] PP: per-protocol.

[e] NR: not reported.

[f] ITT: intention-to-treat.

[g] GA: gestational age.

[h] ICBT: internet-delivered cognitive behavioral therapy.

[i] GDM: gestational diabetes mellitus.

Intervention Characteristics

Targeted Health Issue

As shown in Table 2, the interventions in the reviewed studies varied widely. Of the 26 studies, 10 (38%) focused on mental health treatment: 2 (20%) studies focused on web-based mindfulness [45,49], 7 (70%) studies focused on various psychological treatments [42,43,46,48,50,51,53], and 1 (10%) study focused on insomnia [31]. Furthermore, 19% (5/26) of the studies examined antenatal care interventions: 1 (20%) for nonspecific pregnant women [40] and 4 (80%) for those with GDM [35,37,47,52]. Education was the focus of 11% (3/26) of the studies, with 1 (33%) study focusing on diabetes diet education [29] and 2 (33%) studies focusing on general pregnancy health education [36,54]. Five studies targeted health behavior interventions, including diabetes dietary intake and exercise management [38,39], prenatal weight management behavior [32,33], and health care for substance abuse and risky sexual behavior [34]. Three studies explored self-help groups, including a web-based community for nonspecific pregnant women [41], a group for pregnant women with substance abuse [30], and a support group for smoking cessation [44].

Intervention Method and Group Type

Overall, 54% (14/26) of the studies used websites for intervention delivery [29,32,33,40,42-47,49-51,53], whereas 19% (5/26) of the studies used instant messaging only [35,36,38,39,48,54]. Various other methods were used in individual studies, such as computerizing intervention authoring systems [34], a mix of websites or mobile apps [31], social network services [41], offline and instant messengers [37], Internet of Things and instant messengers [38], telemedicine systems and SMS text messaging [52], and electronic voice bulletin boards using mobile devices [30]. Six studies targeted groups [30,35,36,41,48,54], and the remaining 20 studies focused on individual interventions.

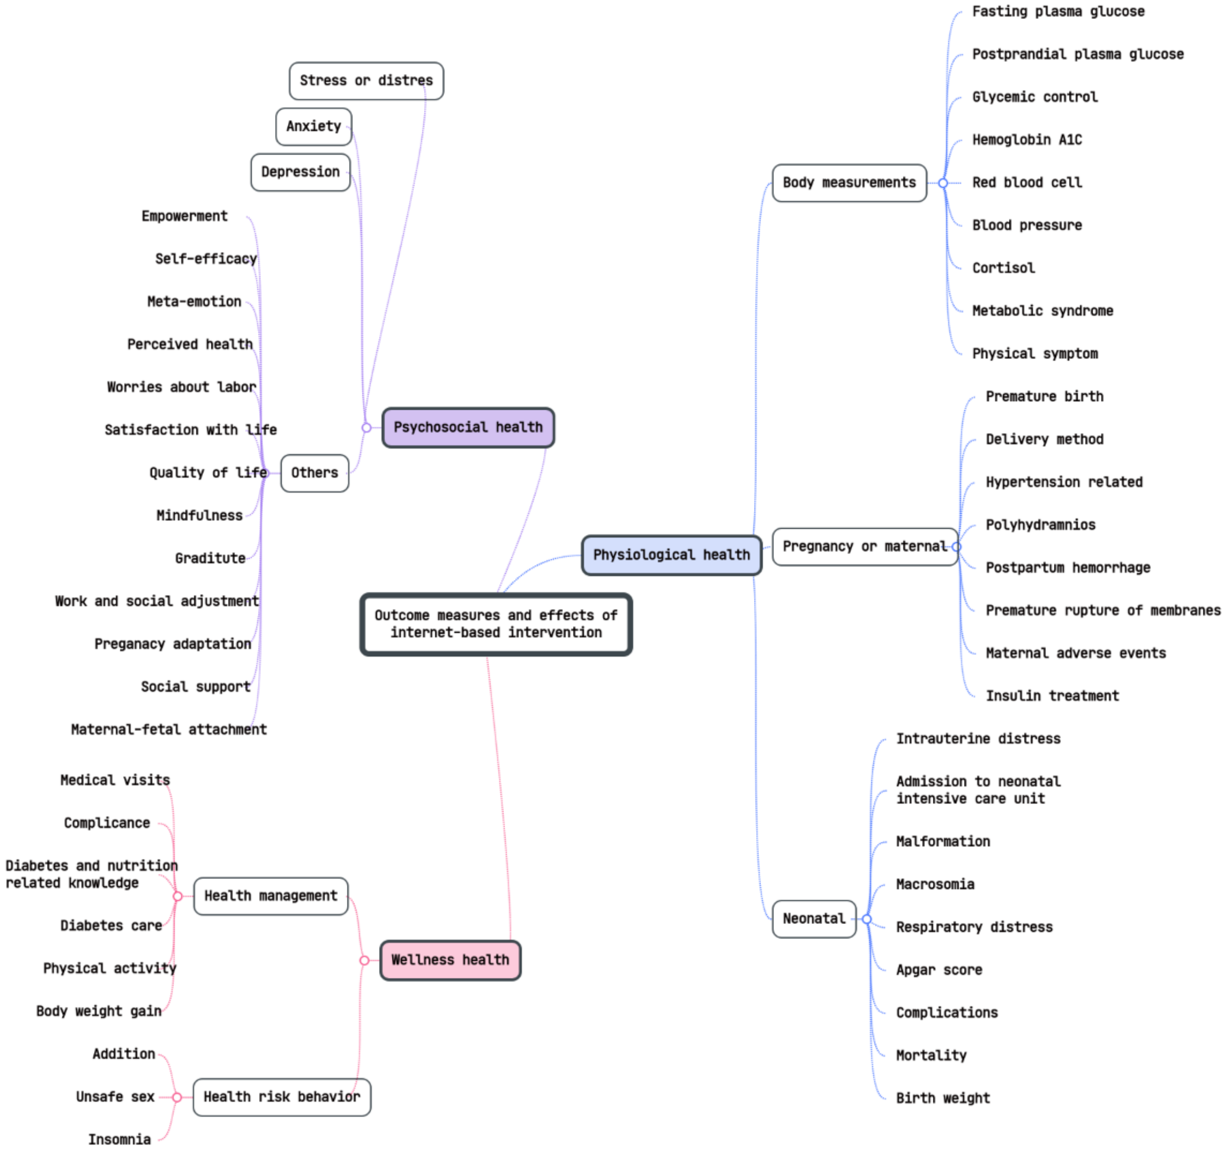
Intervention Timing, Duration, and Comparative Approaches

The timing and duration of the interventions varied across studies. Although no interventions were exclusively conducted during the first trimester, 4% (1/26) of the studies covered the first and second trimesters [49], 88% (23/26) of the studies spanned all trimesters [29-38,40-48,50,52-54], and 8% (2/26) of the studies extended into the postpartum period [39,51]. The duration ranged from ≤4 weeks in 15% (4/26) of the studies [34,45,46,49] to >32 weeks in 4% (1/26) of the studies [54], with 8% (2/26) of the studies not specifying the period [29,36]. With regard to comparative interventions, 50% (13/26) of the studies provided standard care or education to the control groups, such as usual antenatal care [35,38,39,41,51], health education [36,40,54], or typical treatments [31,46,49]. Unique approaches included watching brief television segments with questions [34] and accessing a basic, nonpersonalized website [44]. Of the 13 studies, 12 (92%) did not provide any intervention to control groups [29,30,32,33,37,42,43,45,47,50,52,53] and 1 (8%) did not report the intervention in the control group [48]. This variety in intervention timing, duration, and comparative approaches underscores the diversity in study methodologies and target populations (Table 2).

Outcomes and Effects of Interventions

The outcomes of the interventions, as detailed in Multimedia Appendix 2 [29-54], were divided into 3 main categories: psychosocial, physiological, and wellness health outcomes. Each category encompasses several subcategories, as shown in Figure 3.

Figure 3. Mind map of the outcomes and health impacts of internet-based interventions. BP: blood pressure; NICU: neonatal intensive care unit; RBC: red blood cell.



Psychosocial Health Outcomes

Within this domain, a total of 16 distinct outcomes were identified. These psychosocial health outcomes encompassed a range of factors, including stress or distress, anxiety, and depression, along with a variety of other elements related to mental, emotional, and social well-being.

Stress or Distress

Seven studies assessed stress or distress, with 4 (57%) targeting nonspecific pregnant women [40,45,48,49], 1 (14%) focusing on women with anxiety or depression [46], and 2 (29%) on those with preterm labor [42,43]. Stress or distress was the primary outcome in 6 (86%) of these 7 studies [40,42,43,45,48,49]. Among the 7 studies, 2 (28%) specifically addressed populations with stress issues [42,43], whereas 2 (28%) other studies involved nonspecific pregnant women without preexisting stress issues [45,49]. Significant reductions in stress or distress were observed in the intervention groups of the studies involving nonspecific pregnant women [40,45,48,49]. In a study targeting women with anxiety or depression, a significant reduction in distress was noted 1 week after the intervention, but this effect was not sustained at the 4-week mark [46]. Conversely, interventions in studies involving women with preterm labor did not yield significant effects [42,43].

Anxiety

Of the 9 studies examining anxiety, significant reductions were observed under certain conditions. One study targeting women with GDM reported immediate reductions in anxiety after the intervention [37]. Another study, focusing on individuals with anxiety or depression, noted a significant reduction in anxiety 9 weeks after the intervention [46], and a study targeting those with insomnia observed significant reductions after 10 and 18 weeks [31]. However, no significant changes in anxiety levels were observed in 4 studies involving nonspecific pregnant women [45,48,50,53] or in 2 studies involving women experiencing preterm labor [42,43]. Notably, anxiety was the primary outcome in only 1 of these studies [46].

Depression

In the 10 studies addressing depression, 3 (30%) reported significant reductions: 1 involving nonspecific pregnant women [45], 1 involving women diagnosed with GDM [37], and 1 focusing on individuals with insomnia [31]. A study targeting women with depression [53] found mixed results, with a decrease in 1 of the 2 assessments for depression. However, the interventions did not significantly impact depression in 4 studies with nonspecific pregnant women [41,49-51], 1 study with women having anxiety or depression [46], and 1 study involving preterm labor [42]. Only 3 of these studies measured depression as their primary outcome [50,51,53], and 1 study did not report its results [48].

Other Psychosocial Health Outcomes

This category encompasses various aspects of psychosocial health. Significant improvements were noted in empowerment [48], self-efficacy following meditation [40], and metaemotion [48]. In 4 studies assessing perceived health, no significant effects of the interventions were observed in 1 study involving nonspecific pregnant women [53], 1 study with individuals experiencing anxiety or depression [46], and 1 study with drug users [30]; however, a study involving women with GDM showed significant improvement in concise health status [37]. Individual studies measured labor-related worries [45], life satisfaction [49], and quality of life [46] but found no significant impact from the interventions. Mindfulness increased significantly in 1 of the 3 studies [45,48,49] targeting nonspecific pregnant women. These interventions did not yield significant effects on gratitude [49], work and social adjustment [53], pregnancy adaptation [41], or social support [41]. In studies involving pregnant women with anxiety or depression [46] and nonspecific pregnant women [41], maternal antenatal and maternal-fetal attachments were not significantly influenced by the interventions, respectively.

Physiological Outcomes

This section summarizes the physiological outcomes across 3 categories: body measurement, pregnancy or maternal, and neonatal.

Body Measurement

Nine studies focused on body measurement outcomes. Fasting plasma glucose (PG) levels, assessed in 3 studies, showed significant intervention effects in 2 studies on women with GDM [37,38] but not in women at GDM risk [39]. The 2-hour postprandial PG levels showed significant intervention effects in 2 studies [37,38]. One study reported significant intervention impacts on average glycemic control rates across fasting PG, 1-hour PG, 2-hour PG, and nighttime PG levels [35]. Glycated hemoglobin (HbA_{1c}) levels, measured in 2 studies [38,52], revealed significant intervention effects in 1 study [38]. One study noted significant intervention impacts on red blood cell and hemoglobin levels [38]. However, 2 studies found no significant intervention effects on systolic or diastolic blood pressure [39,52]. Waking and evening salivary cortisol levels showed significant changes [49], but the cortisol awakening reaction did not change significantly in a study targeting nonspecific pregnant women [49]. A study on women with preterm labor, however, showed significant effects [42]. Metabolic syndrome assessments in 1 study [39] revealed significant intervention effects on triglyceride and cholesterol levels, and metabolic syndrome changes, but not on high-density lipoprotein levels or waist circumference [39]. In addition, physical symptoms in nonspecific pregnant women showed no significant changes [41].

Pregnancy or Maternal

Eight studies reported on premature birth; no significant intervention effects were found, including 5 (63%) studies with women with GDM or GDM risk factors [35,37,39,47,52], 1 (13%) study on women with preterm labor [42], and 2 (25%) studies with nonspecific pregnant women [50,54]. In studies involving women with GDM, interventions showed no effect on assisted vaginal [47] or cesarean deliveries [35,39,47]. Three studies reported no impact on hypertension-related outcomes such as preeclampsia [39], gestational hypertension [47], or urine albumin-to-creatinine ratio [52]. There were also no significant effects on polyhydramnios [37], postpartum hemorrhage [35,37], or premature rupture of membranes [35,47]. However, 1 study reported a significant effect of interventions on maternal adverse events [38]. No significant effects were observed on the number of insulin-treated women in 1 study [52], but significant effects were noted on the total contact per insulin-treated woman (total hours) in another study [52].

Neonatal

Five studies involving women with GDM [35,37-39,54] reported on neonatal outcomes. Interventions showed no significant effects on intrauterine distress [37], admission to neonatal intensive care [35,39], malformations [35], macrosomia [35,37], or respiratory distress (neonatal asphyxia) in 2 studies [35,37], although 1 study reported a significant effect [54]. Significant effects were observed on the Apgar score in one study [38] and on the number of neonatal complications in another study [38]. The effect of interventions on low birth weight was not significant in one study [35], but the effect was significant in another study [39]. Two studies reported significant effects on birth weight [38,39].

Wellness Health Outcomes

This section describes 2 categories of wellness outcome measures used in the studies: health management and health risk behavior.

Health Management

The domain of health management included 6 outcomes. One study focusing on women with GDM reported a significant increase in the frequency of medical visits [47]. In another instance, the use of WeChat for health education and schedule reminders led to an increase in prenatal examinations [36]. Notable improvements in adherence to dietary standards were observed in a separate study [38], although another study found no significant impact of diabetes and nutrition-related knowledge [29]. The effectiveness of internet-based interventions was also evident in a study that focused on the diabetes care profile, demonstrating significant positive outcomes [37]. Furthermore, a web-based intervention aimed at enhancing physical activity resulted in significant increases in 20- and 30-minute sessions of moderate to vigorous activity per week [33]. Body weight gain, an important metric in maternal health, was assessed in 4 studies [32,33,39,52]. One study found no significant effects on several metrics, including the percentage of women exceeding the upper limit of the total gestational weight gain (GWG) guidelines at 28 weeks of gestation, the rate of GWG from 32 weeks until delivery, and the total GWG during this period [32]. Meanwhile, 2 other studies observed no significant changes in overall body weight [39,52], yet 1 study highlighted significantly lower BMI changes in the intervention group between 36 and 40 weeks of gestation and better weight recovery of 6 to 12 weeks post partum [39]. Another study, which found no significant effects on total GWG and the percentage gain according to the Institute of Medicine recommendations, reported significant improvements in adherence to these GWG guidelines [33].

Health Risk Behavior

Three outcomes were included under health risk behaviors. In the area of addiction, encompassing drug or alcohol use, one study found no significant differences between the intervention and control groups [30], whereas another study noted a significant difference over time [30]. A study on smoking cessation among pregnant women reported no significant effect on 4-week smoking abstinence [44]. Similarly, no significant differences were observed in a study examining condomless vaginal sex [34]. The severity of insomnia, a concern during pregnancy, showed inconsistent results in 2 studies [31,53]. While one study targeting pregnant women found no significant effect on insomnia severity [53], another study focusing on pregnant women with insomnia documented significant improvements in insomnia symptom severity, sleep efficiency, and sleep quality following the intervention [31].

Discussion

Principal Findings

This systematic review presents a comprehensive evaluation of web-based intervention studies focused on the prevention of premature birth in pregnant women. Various web-based interventions and diverse groups of pregnant women were included in the analysis; however, a significant gap was noted in studies that directly confirmed the effects of these interventions on premature birth. The measurement variables used to ascertain the direct effects of the interventions varied, and there were few well-designed interventional studies. These findings echo those of a meta-analysis of web-based educational interventions in 2022 [55]. Among the analyzed studies, only 12% (3/26) of the studies had an overall low RoB. Many of the included studies had moderate to high risk, primarily owing to nonblinding, adherence issues, and selection bias. This highlights the need for more high-quality intervention studies in this field. Blinding in internet-based intervention studies poses a challenge because of the active participation requirement and common attrition. Consequently, RCTs may not always unfold as intended. Thus, statistical analysis requires adjustment for participant bias, and participant characteristics should be carefully considered during interpretation.

This study found that most web-based interventions primarily used websites, followed by mobile instant messaging, aligning with common methods used in web-based health education interventions [56]. Only 1 intervention in this review used a mobile app [31], although it predominantly relied on mobile instant messengers for information delivery and encouraging participation. This approach is prevalent in countries such as China, Taiwan, Thailand, and Iran [35-39,48,54]. Recent studies, including 1 study using WhatsApp with a chatbot for health promotion messages, have shown higher uptake rates for interventions [57]. Mobile apps, being more accessible than websites, have shown greater effectiveness for glycemic control [11]. Further studies should thus compare the efficacy of websites and mobile apps and explore the use of mobile instant messengers and apps in more depth.

Premature births have many unexplained causes, with preeclampsia, eclampsia, intrauterine growth restriction, spontaneous preterm labor, and preterm premature rupture of membranes being the common causes [58]. Nonspecific pregnant women were the most common target group in the reviewed web-based interventions, followed by pregnant women with GDM, preterm labor, substance use, depression, and anxiety. However, experimental research on women with specific health issues is lacking. Although 7 experimental studies focused on pregnant women with GDM, highlighting the importance of blood glucose (BG) self-management, none targeted women with hypertensive disorders, which is crucial for early detection and management. Furthermore, despite spontaneous premature labor and preterm premature rupture of membranes being leading causes of premature birth [58], only 2 experimental studies [42,43] focused on these conditions. Hence, there is a critical need for further experimental studies targeting pregnant women with specific health conditions.

In most of the reviewed studies, interventions spanned the entire duration of pregnancy, likely because of the increasing risk of premature birth as pregnancy progresses. These web-based interventions typically lasted for 4 to 8 weeks, with a few studies using longer durations. This contrasts with web-based interventions for nonpregnant adults, where longer durations are more common [59]. Given the evolving physical conditions during pregnancy, there is a growing need for long-term interventions that cover the entire pregnancy period, aligning with the emphasis on a holistic approach to pregnancy health care [60]. This approach encompasses not only the pregnancy period itself but also the early and prepregnancy stages as well as the postpartum period. Web-based interventions offer the advantage of accessibility and flexibility, making them suitable for long-term implementation compared to in-person interventions. However, the conclusive impact of the intervention duration remains to be determined, indicating the need for further research.

Our research found that the interventions had varying effects on stress or distress among different groups of pregnant women. Studies involving nonspecific pregnant women [40,45,48,49] and those focusing on women diagnosed with anxiety or depression [46] reported significant reductions in stress or distress following the interventions. This success can partly be attributed to the interventions being tailored to the specific needs of these groups. For instance, the study by Loughnan et al [46], which applied self-guided cognitive behavioral therapy, was specifically designed to target anxiety and depression, closely aligning with participants' conditions. In contrast, interventions aimed at pregnant women with preterm labor did not achieve a similar reduction in stress or distress [42,43]. This disparity may be owing to the interventions in these studies, which were led by Scherer et al [43] and Urech et al [42], not being adequately customized to meet the unique needs of patients experiencing premature labor. Given that the condition of premature birth was not directly addressed [42], it is possible that the programs were less effective for these participants. In addition, as gestational age increased and fetal maturation progressed, the health risks for the newborn decreased [42], which might have influenced the perceived stress levels and the efficacy of the interventions.

The studies included in this research used various interventions, such as cognitive behavioral management [42,43,45,46,49], unified transdiagnostic treatment [48], and antenatal care system [40]. Each of these approaches has its own theoretical basis and methodological implications, which could affect the outcomes. Furthermore, the studies used different stress assessment tools, including the Perceived Stress Scale, Pregnancy Stress Rating Scale-36, and Prenatal Distress Scale. It is important to note that these are self-report screening questionnaires and not diagnostic assessment tools evaluated by trained professionals. This raises questions about the generalizability and applicability of the findings to individuals clinically diagnosed with stress or distress.

The interventions showed significant effects on anxiety in studies targeting women with anxiety [46], GDM [37], and insomnia [31]. However, no significant effects were noted in studies targeting women with preterm labor [42,43]. This aligns with the earlier findings regarding stress. The diversity of the interventions and measurement tools used across the studies, particularly as only 2 studies used the same tools [45,53], indicates the need for further research to reliably estimate these effects on anxiety. In addition, concerning depression, the cognitive behavioral interventions did not significantly impact pregnant women with anxiety or depression [46] or those with preterm labor [42] assessed by the Edinburgh Postnatal Depression Scale (EPDS). Similarly, women with depression [53] showed no significant changes when evaluated using the EPDS, though different results emerged from the Montgomery-Åsberg Depression Rating Scale. Furthermore, 2 studies targeting depression in general pregnant populations [50,51,53] used the EPDS but reported no significant effects [50,51]. The EPDS, although effective in detecting postpartum depression, might be less sensitive in identifying severe or prenatal depression [53]. Notably, in women with insomnia [31], depression significantly decreased when assessed with the EPDS and treated with cognitive behavioral methods. This raises questions about the validity of the EPDS during pregnancy, especially for those at a high risk for depression. Furthermore, most internet-based interventions for depression in pregnant women did not yield effective outcomes as measured by the EPDS. Ashford et al [61], however, claimed its effectiveness in perinatal depression. This discrepancy could be owing to differing methodological qualities; the studies in this review had a high overall RoB, whereas Ashford et al [61] included studies with average to high methodological quality.

This review underscores a notable inconsistency in the types of interventions, target audiences, and assessment tools used across the studies examined. Dennis [62] emphasized the importance of preventive interventions for mental health issues in pregnant women, particularly advocating for targeting women with identified risk factors [63]. In our analysis, the limited effects of interventions aimed at reducing anxiety or depression among nonspecific pregnant women [50,51] could be attributed to the absence of specific risk factors for these conditions. This observation suggests that the effectiveness of preventive psychosocial health interventions may be enhanced by tailoring them to the needs of women with identifiable risk factors.

Most studies in our review focused on verifying the effectiveness of BG control in women with GDM. The research demonstrated significant effects on both fasting BG and 2-hour BG levels in several studies [11,22,23,64], aligning with the findings from previous meta-analyses. However, variations were observed, such as in 1 study using a telemedicine system where HbA_{1c} levels were significantly lower in the experimental group [65]. Conversely, a study that provided educational information on GDM did not show a significant impact. These discrepancies might be because of factors such as the duration of the interventions, sensitivity of the indicators used, and the limited number of trials conducted. The physiological changes during pregnancy, such as iron deficiency and reduced life span of red blood cells, can affect the sensitivity of HbA_{1c} assays [65]. In contrast, glycated albumin, with a shorter half-life, may offer a more accurate measure of short-term glucose fluctuations. However, research on glycated albumin in pregnant women is still limited [11], suggesting an area that warrants further investigation in the future.

In terms of preventing premature birth, interventions targeting women with GDM or those at risk for GDM did not demonstrate a significant effect on this outcome [35,37,39,42,47,50,52,54]. These studies primarily assessed the role of internet-based intervention in addressing the causes of premature birth, analogous to managing diabetes for blood sugar control. The complexity of factors influencing premature birth makes it challenging to ascertain the direct preventive effects of these interventions. Hence, premature birth was not the primary outcome in any of the reviewed studies. Given the insufficient number of studies specifically examining each intervention type, it becomes necessary to continue evaluating premature birth as a secondary outcome in future research. This approach will further our understanding of how interventions can mitigate or eliminate the causes of premature birth, thereby enhancing maternal and neonatal outcomes.

Strengths and Limitations

This systematic review contributes to the literature by methodically analyzing internet-based interventions aimed at preventing premature birth. Its main strength lies in its extensive focus on a broad spectrum of outcomes, covering a wide range of maternal and neonatal health aspects. Another key strength is the inclusivity of the review, encompassing a diverse range of populations. The absence of geographical or language restrictions in the selection criteria enhances the comprehensiveness and global applicability of the review. This broad and inclusive approach not only illuminates the potential of internet-based interventions in the pregnancy context but also delineates their limitations, thereby laying a foundation for future research endeavors and informing clinical practice with a more global perspective.

However, the review has several limitations that need to be considered. Its reliance on studies from only 4 databases may have missed relevant research from other sources, potentially limiting the scope of the findings. The exclusion of specific types of publications, such as conference abstracts and dissertations, coupled with limited responses from original authors for additional data, could have introduced publication bias. In addition, 2 studies translated from non-English language using Google Translator may have inaccuracies in translation, affecting the interpretation of these studies. Although backward and forward citation tracking of the final included articles was initially planned, it was not conducted because of resource constraints and the comprehensive nature of the initial search. The underrepresentation of studies with a low RoB in this review suggests the need for caution in generalizing the results. Moreover, the focus on studies predominantly from countries with high internet use may limit the applicability of the findings to regions with different internet access levels and use patterns. Therefore, the results should be interpreted with an understanding of these contextual differences.

Conclusions

This systematic review uncovered a wide array of internet-based interventions that target risk factors associated with premature birth, with notable efficacy in the realms of psychosocial health and blood sugar management. However, interventions addressing other risk factors have shown a considerable diversity in measurement methods and a range of experimental effects. This variability points to an ongoing challenge in accumulating robust evidence. These findings underscore the critical necessity for future clinical trials to not only develop and test but also widely disseminate internet-based interventions that are both safe and effective. In addition, there is a pressing need for the creation of standardized measurement tools. Rigorous evaluation processes should be established to enhance the effectiveness and reliability of these interventions in clinical settings. Such efforts are essential for ensuring that these digital health solutions can effectively contribute to the prevention of premature births and improve maternal health outcomes on a broader scale.

Acknowledgments

This research was supported by the Basic Science Research Program through the National Research Foundation of Korea, funded by the Ministry of Education (2021R1I1A3047489). The funder had no role in the study design; collection, analysis, and interpretation of data; or writing of this manuscript.

The authors would like to express their deepest gratitude to Sunyoung Park (Professor, Daegu Catholic University) for her help with the data search.

Authors' Contributions

SHK, SYJ, and JHP developed the research questions. SHK was responsible for the methodology design and leading the review process. The review process, including resolving discrepancies, screening and selecting studies, and extracting and coding data, was jointly conducted by SHK, SYJ, and JHP. Descriptive analyses and the preparation of tables and figures for the manuscript were conducted by SHK, JHP, and JCDG. All authors were involved in the interpretation of the findings. Initial drafting of the manuscript was done by SHK and JCDG. The manuscript was revised and the final version was approved by all authors.

Conflicts of Interest

Abstract

Background: There was a marked decline in child and teenage mental health worldwide during the pandemic, with increasing prevalence of depression, anxiety, and suicide. Research indicates that positive psychological interventions may be beneficial for mental health.

Objective: The aims of this review were to evaluate positive psychological interventions for child and youth mental health implemented during the COVID-19 pandemic and assess overall effectiveness for mental health and knowledge.

Methods: We undertook a literature search of PubMed, MEDLINE, and Google Scholar for all eligible studies on digital and hybrid in-person psychological interventions for youth mental health during the COVID-19 pandemic. A particular emphasis was placed on positive psychological interventions or interventions that had components of positive psychology, including gratitude, acceptance, positive emotions, or resilience building.

Results: A total of 41 interventions were included in this review. Most of the interventions were digital. Overall, most of the interventions assisted with one or more mental health or psychological indicators, such as depression, anxiety, posttraumatic stress disorder, stress, and resilience. However, findings were mixed when it came to targeting both depression and anxiety together. The interventions that promoted youth mental health most often had a range of diverse positive psychology components and were evidence based. Not all studies measured changes in mindfulness. Few studies examined knowledge acquired on mental health self-care, managing mental health problems, knowledge of positive psychological techniques, mindfulness knowledge, or mental health self-efficacy.

Conclusions: Diverse multicomponent interventions appear to assist with youth mental health overall, although their effects on both depression and anxiety are less clear. There is also a need for more research on knowledge gains to determine whether the interventions improved knowledge on mental health–supportive behaviors, which may be sustained beyond the intervention. Finally, more studies need to evaluate whether the interventions assisted with increasing self-efficacy for practicing positive psychological techniques as well as changes in mindfulness levels. Future studies should not only assess effectiveness for mental health outcomes but also assess knowledge translation, with valid measures of knowledge and self-efficacy for mental health–supportive behaviors and positive psychological skills acquired (eg, the ability to practice mindfulness).

Introduction

Background

Worldwide, there was an increase in mental health problems in children and teenagers, including increasing rates of depression, anxiety, and suicide, during the global COVID-19 pandemic [1]. Systematic reviews have estimated the global prevalence of childhood and teenage depression at 23% and anxiety at 28% [2], whereas the prevalence of suicidal ideation was estimated to be 29% to 33% in this age group [3]. A study in Australia found an increase in the use of helplines for kids to cope with mental health issues [4]. Higher levels of isolation were reported in children and teenagers resulting from the closure of schools and reduced socialization with peers, coupled with challenges stemming from reduced access to mental health services [1,5]. Moreover, data from the World Health Organization (WHO) indicate that there were barriers to accessing mental health care services, particularly among children and teenagers, who experienced a 72% disturbance in their mental health care, with counseling and psychotherapy being the leading services that were affected during the transition to digital care [6].

Given the serious consequences for child and youth mental and psychological health, there is a need to evaluate what strategies were effective for buffering against the deleterious impact of the pandemic. Without understanding what measures were effective for helping children and youth cope and adjust to the "new normal" gaps and barriers will remain when it comes to future pandemic preparedness in relation to mental health crises in this population.

A systematic review comparing the prepandemic and pandemic periods found that youth experienced higher levels of isolation, depression, and anxiety during the pandemic [7]. Data from the WHO suggest that children from economically-deprived backgrounds were impacted the most [8]. Research also suggests that certain personality and neurodevelopmental types were differentially affected during the pandemic. For example, research has found that children with neurodevelopmental disorders had higher anxiety during the pandemic [9] and that siblings often provided social support for distressed children with disabilities [10]. In addition, a systematic review found that some children experienced boredom during the pandemic [11], which was also found in other studies among neurotypical individuals [9,12,13].

The pandemic also created challenges for parents in terms of adjusting to learning from home [14]. Research from the All Our Families cohort in Calgary, Alberta, also found a rise in depression by 3.2 points and in anxiety by 2.39 points in mothers during this period when compared with the 3-year period before the pandemic [15]. They struggled with managing homeschooling, lack of daycare, and financial troubles [15].

Research from the WHO indicates that social support was a major buffer for promoting mental well-being in children and teenagers during the pandemic [8]. The prevailing literature also suggests that self-care, positive psychological states, and resilience have protective effects on well-being, stress management, and mental health [16-23]. Positive psychology is described as a state of flourishing and thriving even when experiencing health problems or hardship by living one's best life [19]. Individuals who have high levels of positive mental health and resilience [24] and who score high on resilience tend to have lower levels of depression [24] and anxiety [23]. Individuals with high levels of positive mental health are 27 times more likely to recover from mental health issues relative to their counterparts with low levels of positive mental health [25]. Furthermore, positive mental health has been found to be a buffer for suicide prevention in patients with depression [26].

Positive psychology is relevant to children and youth in relation to their mental health during the pandemic. Positive psychology can help youth by providing them with the necessary tools and resources to increase their resilience, well-being, and ability to cope during difficult times, which is especially relevant to the global youth mental health crisis during the pandemic [16-23]. Individuals can be struggling with mental health problems, yet they can demonstrate resilience and flourish. Flourishing focuses on thriving amidst hardship by living one's best life even when experiencing metal health problems or other difficulties [18,19] and is particularly relevant for youth, given the mental health crisis worldwide [18,19]. Flourishing has several essential elements, which include life satisfaction, meaning or purpose in life, character or virtues, and positive affect. It also includes happiness, social relationships, and mental health [27-29].

Resilience is a form of internal coping in one's given environment regardless of external stressors that one may encounter [30]. Resilience has also been found to be inversely related to mental health problems and a buffer against stress [21]. Building resilience and helping youth find ways to flourish include assisting youth in acquiring the skills and tools to cope during difficult life circumstances [20]. Considering the relevance of positive psychology and its components for youth mental health, more research is needed to better understand the types of positive psychological interventions that have been developed, including ones that aimed to increase flourishing and build resilience in youth during the COVID-19 pandemic and their overall effectiveness for mental health.

In addition to positive psychology, there are also psychological interventions that are closely connected to it and potentially of great importance for youth mental health during the pandemic. Research indicates that mindfulness, a form of present-moment awareness using formal and informal meditation, may help build resilience through greater self-awareness, acceptance, kindness, and gratitude [31]. Mindfulness also has elements that are of great importance to positive psychology, including self-acceptance, compassion, positive emotions, and gratitude [32,33]. Research also indicates that mindfulness practice may help with the development of compassion and reducing stress, anxiety [34], and depression [10-13]. Studies have further found that, when students are more mindful, they can learn more in the classroom and be more focused on given tasks and are more creative [14,15]. Mindfulness is of relevance to mental well-being in children and youth during the pandemic [34]. Cross-sectional research on mindfulness in children has found that higher levels of mindfulness (children who were more mindful) were linked to higher coping during the pandemic [34]. Even with the pandemic coming to an end, young people may still face hardship and personal crises, and there is a need to provide them with coping skills.

Finally, research has found that higher levels of social support, coupled with positive coping strategies, were protective for youth mental health during the pandemic [35]. Recommendations for helping children and adolescents have included developing coping strategies as well as receiving social support from family members [2]. Thus, investigating interventions that have assisted youth with positive coping and psychological and social support during the pandemic to promote youth mental health can inform strategies for future mitigation of mental health concerns in other crises.

Furthermore, to the best of our knowledge, there has not been a review that has evaluated what types of positive psychological interventions have been undertaken for youth mental health, including their fundamental components and whether they were effective for alleviating mental health and psychological indicators such as resilience, stress, and well-being during times of unprecedented crises, stemming from the pandemic.

In addition to traditional positive psychological interventions, there also has not been a review that has explored psychological interventions that have common elements that are related to traditional positive psychology, such as gratitude and resilience building [32,33]. Thus, it is also of interest to explore interventions that contain elements that are related to positive psychology, such as mindfulness, which focuses on self-acceptance, compassion, and gratitude, among other things [32,33]. Some experts also argue that cognitive behavioral therapy (CBT) has important elements that are of fundamental relevance to positive psychology, including its focus on positive emotions [36], hope, and strength building, highlighting that it is useful to include interventions that are informed by CBT as well. In recent times, there has also been a shift toward a "positive CBT" model of care whereby the core treatment focus is on positive aspects exclusively [37].

In addition, little is known about the uptake of mental health–promoting behaviors, such as mindfulness, from positive psychological interventions. For example, studies have examined whether mindfulness interventions assist with mental and psychological health but have not measured knowledge levels, and few have measured changes in mindfulness [38,39]. There is a need to investigate whether positive psychology interventions help youth with gaining important knowledge surrounding mental health as well as techniques derived from positive psychology, such as mindfulness for self-care. Mental health literacy has also been found to be an important determinant of help-seeking behaviors [40], and exploring it in relation to positive psychological interventions in youth during the pandemic is of research interest. Understanding whether the interventions effectively disseminated knowledge on self-care in relation to mindfulness and knowledge of positive psychological techniques to assist with coping is also important. Often, research is not translated into practice [41], and developing effective knowledge dissemination strategies enables evidence-based research findings to take shape in the community through increased awareness and greater adoption of these mental health–promoting resources and behaviors.

Objectives

This review had the following aims:

1. To better understand what positive health psychology interventions (including resilience and flourishing focused), as well as interventions that have common elements related to positive psychology (eg, mindfulness-based interventions or CBT-based interventions [36]), were developed during the pandemic and their overall effectiveness for youth mental health, including depression, anxiety, and well-being.
2. To better understand whether the psychological interventions increase levels of mindfulness and resilience in youth.
3. To better understand whether the psychological interventions increase knowledge of positive psychology practices, including knowledge levels of mindfulness in youth and knowledge of mental health self-care behaviors. In other words, did the interventions assist with knowledge translation (KT) on how to practice self-care and resilience coping skills?

Methods

Study Design

A literature search was undertaken in PubMed and MEDLINE for all relevant studies on traditional positive psychological interventions or psychological interventions with elements that are common to positive psychology for child and youth mental health during the pandemic, using the PRISMA-P (Preferred Reporting Items for Systematic Reviews and Meta-Analyses for Protocols) guidelines [42]. Google Scholar and manual hand searches were also undertaken to identify any additional studies.

Inclusion and Exclusion Criteria

All positive psychological interventions studies on children (aged <10 years), preteenagers (aged 10-12 years), teenagers (aged 13-18 years), or youth and student mental health (ages of 18-24 years) were included if they were undertaken during the pandemic period (March 2020 to December 2022). The search was undertaken in December 2022 and recently updated in July 2024 to capture additional studies that were undertaken during the pandemic but published at a later date. Studies that were designed before the pandemic but evaluated the effects of the intervention during a period of the pandemic were also included. We included mindfulness-based interventions, CBT, flourishing, and resilience, among other interventions that fell under the positive psychology umbrella for youth mental health. Reviews were excluded, as well as articles that were not published in peer-reviewed journals. Studies must have been published in the English language to be included. Qualitative studies were excluded. Studies must have been interventional in design, such as randomized controlled trials (RCTs) or quasi-experimental 1-arm pretest-posttest designs. Pilot RCTs were included. Studies on program implementation or health care service delivery experiences or perspectives were excluded. Only studies that evaluated the effectiveness of positive psychological interventions were included.

Search

A medical librarian assisted with the search strategy. Keywords included word variations for “mindfulness” or “intervention” and “mental health” or “flourishing” or “resilience” or “stress” or “positive psychology” and “young adult” or “teenager” or “youth” and “knowledge” or “knowledge translation.” The population included young adults, children, and teenagers. The interventions included positive psychological interventions, mindfulness-based interventions, and CBT, among others. The outcomes included depression, anxiety, stress, and resilience, among others. The comparator included a control group (standard or usual care), but single-arm pretest-posttest studies did not have a comparator. Word variations for each outcome, intervention, and population were entered into the search. The search was rerun and updated again in July 2024 to ensure that all relevant studies were still included. An example of the search strategy is detailed in Textbox 1.

Textbox 1. PubMed search strategy example.

Screening and Data Extraction

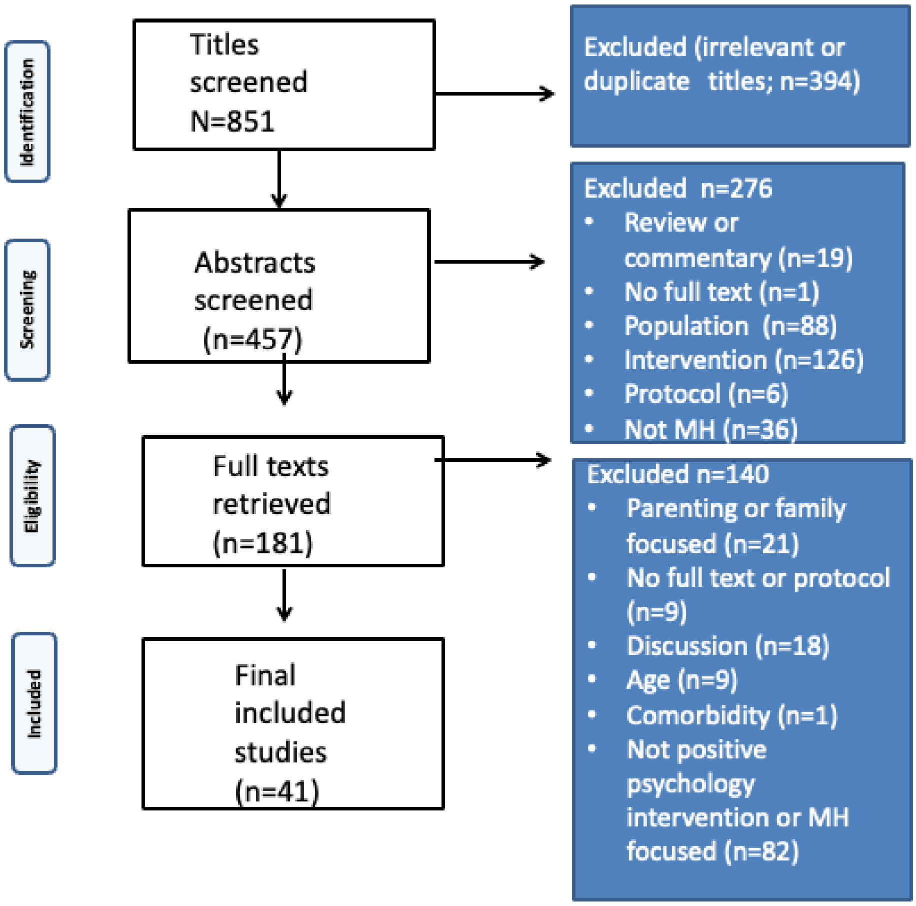
Titles were screened for relevance followed by screening of abstracts against the inclusion and exclusion criteria, followed by retrieval of full-text articles. Full texts meeting the inclusion criteria were included in the review. Data were extracted and summarized in tabular format. This included the study general characteristics, measures, outcomes (mental health), positive psychology intervention types, mindfulness attributes, behavior change techniques, intervention details, and knowledge.

Results

Overview

A total of 41 psychological interventions targeting youth during the pandemic met the inclusion criteria and were included in the review [43-83] that were either purely positive psychological interventions or had common elements that are of great relevance to positive psychology. The results are summarized in Multimedia Appendix 1 [43-55,57-74,76-78,80-83]. Most of the interventions were delivered digitally during the pandemic. The interventions included web-based interventions, mobile health apps, videos, web-based audios and lectures, and emails. In total, 3 were apps, of which 2 were chatbot apps [45,52,60]. A total of 5% (2/41) of the interventions were delivered over WeChat (Tencent) [54,66]. The studies spanned the United States, Canada, Australia, the United Kingdom, Italy, Portugal, Spain, China, Iran, Tunisia, and Vietnam. The search, including the screening process, is illustrated in Figure 1.

Figure 1. Primsa flow chart.



Intervention Content

Almost all of interventions were digital, with the majority being delivered through a web-based mobile health app-based platform [45-47,49-56,58-68,70-73,76,79-82]. Several studies were of mindfulness-based interventions or included mindfulness components [43,44,46,50-52,56,57,60,66-69]. Some of these interventions combined various elements of mindfulness, such as acts of gratitude, breathing, and meditation, whereas 5% (2/12) included mind-body movement with yoga [44,45]. In total, 7% (3/41) of the interventions included more formal mindfulness techniques derived from mindfulness-based stress reduction (MBSR) [43,56,66]. There were also several CBT based studies [54,55,58,59,61-65], as well as mixed hybrid CBD studies involving other techniques such as combined CBT with dialectical behavior therapy (DBT) [65] and combined mindfulness with CBT [62,64]. A few of the studies had a social support component, with one comparing CBT with social support informed by the social identity framework [48], another including social support with DBT and other positive psychology principles [65], and a third including social support with mindfulness [57]. One study had a spiritual element, focusing on prayer with a counselor along with meditation [49]. Additionally, a few of the studies combined several different positive psychological components, such as positivity, compassion, and meaningful engagement [53] or self-care, compassion, and meditation [47].

Positive Psychological Interventions for Youth Mental Health

Overview

Overall, almost all of the psychological interventions targeting youth mental health had positive results on one or more mental health outcomes, but a monitory of the studies did not find that the interventions were effective for any of the measured mental health outcomes [44,50,51,67]. The studies with negative findings often tended to not include a thoroughly described program and theoretical underpinning. For example, they did not describe the details of the mindfulness program [50] or vaguely described informal mindful photography practice with acts of kindness [51] or mind-body movement with breathing [44] rather than relying on evidence-based structured programs with mindfulness techniques that were described in greater detail.

Effects on Depression

Many of the studies that measured depression found that the interventions improved depression [43,45,53,54,58,59,61,65,66,68,71,73,74,77,80], but a minority not find that the interventions assisted with depression [62,64]. Of these studies, some were on mindfulness-based interventions [43,66,68], while others were predominantly CBT interventions [54,59,61,65], with one combining resilience with CBT training [61] and another combining CBT with DBT [65]. In addition, one was a multicomponent positive psychological intervention [53], whereas another was a yoga intervention [45]. Social support was found to be superior to CBT in one study for depression [48], whereas another study found that social support was as effective as mindfulness for alleviating depression even though mindfulness was helpful [66]. A web-based intervention involving Ipsha yoga with audios, found that depression was alleviated in the intervention arm but only at week 2 [45].

Effects on Anxiety

Several of the studies that measured changes in anxiety found that the positive psychology interventions assisted with anxiety. Of the studies that demonstrated effectiveness, one was a multicomponent positive psychological intervention [53], several were mindfulness-based interventions [43,52,64,66,70,72,82] as well as CBT based [54,55,58,59,63,64,73,74,77].

Effects on Both Anxiety and Depression

Although several studies found independent effects of the interventions on improving either depression or anxiety, some studies had mixed findings with regard to the effects of the interventions on effectively targeting both depression and anxiety. In other words, some studies found that the interventions assisted with both depression and anxiety together, whereas others did not. Several studies found that the interventions were effective for decreasing both depression and anxiety [43,53,54,58,59,66,73,74,77]. For example, the 8-week MBSR randomized pilot study in 49 participants by An et al [43] found that the intervention reduced depression and anxiety by 40% and was associated with changes in the brain on electroencephalogram readings. In addition, one study was a multicomponent 8-week positive psychology RCT involving 366 participants and found reductions in depression and anxiety [53].

A few studies did not find that the interventions reduced both anxiety and depression together [45,61,64,70,80,81]. For example, the 4-week MBSR with mindfulness-based cognitive therapy (MBCT) RCT (N=144) by Sun et al [66] found reductions in anxiety but not depression in the intervention arm relative to the control arms. Furthermore, while the 4-week CBT RCT (N=585) by Rackoff et al [61] found that the intervention reduced depression, there were no substantial changes in anxiety. In contrast, the 8-week CBT RCT (N=177) by Simonsson et al [64] found reductions in anxiety but not depression in youth. Both studies had some elements of mindfulness. In addition to this, the 8-week web-based CBT plus mindfulness intervention by Ritvo et al [62] did not have any significant effects on depression or anxiety. This contrasts with a CBT chatbot app that reduced depression and anxiety levels in youth [54].

Effects on Posttraumatic Stress Disorder

A total of 4% (2/41) of the studies evaluated the effects of the positive psychology interventions on posttraumatic stress disorder (PTSD) in youth during the pandemic and found significantly lower levels of PTSD in intervention participants relative to controls [57,59].

Positive Psychological and Derived Interventions for Youth Psychological Stress and Well-Being

Most of the studies that evaluated stress found that stress was reduced in youth after the psychological interventions [43,45,46,49,52,53,61,62,68], but it should be noted that one of these studies found only marginal effects [52]. Well-being was also higher in the intervention arms relative to the control groups in a few studies that assessed it [45,46,53]. Youth also scored higher on various emotional facets and character traits, including positive affect [45], hope, optimism, emotional regulation [53], forgiveness [60], and life satisfaction [60].

Flourishing and Its Core Elements: Affect, Life Satisfaction, Character, Meaning, and Relationships

We did not find any positive psychology interventions that measured and evaluated human flourishing in youth at baseline and follow-up during the pandemic. However, a minority of the positive psychology interventions included fundamental elements of human flourishing from its core definition [27,29]. This included character, positive emotions, meaning, happiness, purpose, life satisfaction, social relationships, affect, and mental health [28,52,53,61,62].

The study by Krifa et al [53] found that multiple positive psychological interventions may be superior for youth mental health by combining compassion, positivity, and meaningful engagement in a digital intervention. Although they did not directly measure flourishing, these elements are fundamental complements of flourishing [53]. The 2-week RCT (N=250) by Dupont et al [51] focused on small acts of kindness, gratitude, and mindful photography, although the study did not have significant effects on any mental health outcomes of interest. The 2-week RCT (N=164) by Pizarro-Ruiz et al [60] involved an app that promoted positive affect, life satisfaction, and forgiveness. Similarly, the study by Rackoff et al [61] targeted positive affect but also included elements that focused on building healthy relationships and coping skills and finding a greater meaning in life. The 8-week RCT (N=154) by Ritvo et al [62] combined mindfulness with other positive psychological elements linked to flourishing, including life satisfaction, healthy relationships, coping skills, and a healthy lifestyle. Similarly, the 4-week pretest-posttest study by Gabrielli et al [52] (N=71) combined mindfulness with behavioral coping strategies that assisted with emotional regulation. The 4-week RCT (N=190) by Dorais and Gutierrez [49] focused on meaning and purpose in life through prayer.

Knowledge Uptake

Almost none of the studies evaluated knowledge dissemination and uptake levels for mental health knowledge and self-care knowledge, among other key knowledge-related domains relevant to the positive psychology interventions. Only one of the studies, the study by Sun et al [66], evaluated knowledge in relation to self-care, regulating emotions, the mind and body, and coping with stress. The study by Sun et al [66] found that knowledge of self-care behaviors, emotional regulation, and stress coping improved after the intervention. Although one study found that participants had higher levels of emotional regulation, it did not assess knowledge levels [53]. In addition, only one study evaluated motivation to learn and found that participants were motivated to continue to learn about self-care in a compassion, self-care, and meditative intervention [47].

In addition to knowledge gained and motivation to learn, 4% (2/41) of the studies considered self-efficacy for managing mental health. One study assessed changes in mental health self-efficacy and management but did not find that the intervention increased overall levels [65], whereas another found that mental health self-efficacy increased [58].

Furthermore, none of the studies evaluated self-efficacy to practice mindfulness or other positive psychology techniques, including CBT. Only one study, the study by Sun et al [66], reported that participants had learned how to practice mindfulness, including self-regulation of the mind and body, whereas another study found that participants enjoyed learning the mindfulness modules [52]. This suggests that only a minority of studies considered knowledge and skill acquisition in relation to positive psychological techniques, whereas none considered self-efficacy.

Study Quality

Overall, the studies were of average quality when considering several factors, including those listed by the Cochrane Risk of Bias grading tool [50]. The study duration ranged from 2 weeks to 1 year. Mindfulness-based interventions are traditionally 8 weeks in duration; hence, studies shorter than this were graded as weak [84]. Most of the studies were RCTs. Blinding was usually not undertaken except in a few studies in which the assessors or participants were blinded, but not both [49,50,60,61]. Most studies had good overall retention levels. Several studies also undertook a priori power calculations, ensuring that they were sufficiently powered with adequate sample sizes to detect a difference if one existed between the intervention and control arms [44,45,49-51,53,54,61,62,66]. In addition, the studies used data collection methods that were valid and reliable, or the questionnaires had been previously used and validated.

Discussion

Principal Findings

We aimed to better understand what positive psychology or positive psychology–derived or related interventions (including ones that had common elements from positive psychology) were implemented to address mental health concerns among youth during the pandemic.

First, we aimed to better understand what types of interventions were implemented and the types of media and techniques that were used. Overall, the interventions that targeted more than one element were more likely to have significant effects on one or more mental health outcomes [53]. The interventions were diverse, often combining various facets of positive psychology along with mindfulness or CBT. Among the interventions, almost all had a CBT or mindfulness component (including informal practice or movement). However, only a minority had a formal mindfulness program derived from MBSR or MBCT, with the rest providing fewer details. The studies in this review included combinations of CBT with mindfulness, combined CBT with resilience training, combined either mindfulness or CBT with social support, as well as combined CBT with DBT. In addition, there was a multicomponent + psychology intervention, informal mind-body movement with yoga interventions, and combined positive psychology with informal mindfulness (eg, gratitude and compassion), and 1 (1/41, 2%) was based on meditative counseling with prayer. We also found that some elements of flourishing, namely, life satisfaction; positive emotions; purpose; and certain qualities, including gratitude, were targeted in the studies. However, none of the studies evaluated flourishing as an entire construct, which could be useful in future positive psychological interventions to determine whether they assist with flourishing.

Second, we further aimed to determine whether the interventions were effective for improving mental health. Overall, the interventions demonstrated effectiveness for improving mental health in youth. Almost all of the interventions helped with one or more mental health outcomes, including depression, anxiety, stress, PTSD, and resilience among youth. Many of the mindfulness-based interventions assisted with depression and anxiety. Previous research has found that mindfulness and CBT are effective for anxiety and depression [85-88], confirming our findings. The prevailing literature on positive psychology also indicates that it helps with resilience and improving positive affect [89,90], which was also found in this review.

Furthermore, the studies were heterogenous in terms of program content, with the interventions that implemented comprehensive media with evidence-based MBSR or MBCT usually showing positive effects compared with interventions that did not elaborate on their programs. Thus, it appears that multicomponent interventions that used diverse media and had greater intervention complexity were more likely to have positive results for mental health in general. For example, only the chatbot study showed significant effects compared with the web-based mindfulness one [52,62]. It could perhaps be that mobile apps for mindfulness combined with other positive psychology elements can best support youth during global crisis times, such as during a pandemic. Previous research has also found that evidence-based mindfulness interventions were effective for depression and anxiety during the pandemic [91].

Although most of the included studies found improvements in depression and anxiety, not all studies in this review helped with alleviating both anxiety and depression together in a single intervention. However, it is important to stress that it is not unusual for interventions to not work simultaneously for both depression and anxiety given their heterogeneity and the fact that there are fundamental differences in the conditions that may require different therapeutic approaches [92]. A few studies did not find that the interventions reduced both anxiety and depression together [45,61,64,70,80,81]. For example, the 4-week MBSR with MBCT RCT (N=144) by Sun et al [66] found reductions in anxiety but not depression in the intervention relative to the control arms. Furthermore, while the 4-week CBT RCT (N=585) by Rackoff et al [61] found that the intervention reduced depression, there were no significant changes in anxiety. In contrast, the 8-week CBT RCT (N=177) by Simonsson et al [64] found reductions in anxiety but not depression in youth. Both studies had some elements of mindfulness. In addition to this, the 8-week web-based CBT plus mindfulness intervention by Ritvo et al [62] did not have any significant effects on depression or anxiety. This contrasts with a CBT chatbot app that reduced depression and anxiety levels in youth [54].

In addition, deciphering why a minority of the studies did not help for either depression or anxiety is challenging as some studies had common interventional content and duration with others that were effective for the same mental health outcomes. For instance, It could be argued that the 4-week CBT intervention that only found improvements in depression needed a longer duration for it to ameliorate anxiety [66], but a similar study of 4 weeks with a comparable sample size found the opposite [61]. It should be noted that this study combined both MBSR with MBCT, which could theoretically indicate that a shorter study requires a more rigorous combined approach, although more research on this topic is needed. It is also worthwhile to consider the intervention media and specific content. The study that only found improvements in anxiety but not depression integrated mindfulness over WeChat and Zoom (Zoom Video Communications) [66], whereas the study that found the opposite used web-based CBT learning modules [61]. From a technology standpoint, one used video-based communication and chat, whereas the other used a web-based medium with courses. It is interesting to note that the intervention that did not find any improvements in depression or anxiety delivered CBT on the web and also offered peer support. Thus, there is insufficient evidence to be able to discern whether specific interventional content, such as the media through which the interventions were delivered, impacted outcomes.

Our review also found that the effects on stress are consistent with the literature on mindfulness and CBT showing a positive effect on stress [88,93]. The reasons for the lack of consistency in studies during the pandemic are unclear. However, the pandemic was an unprecedented time; hence, the global economic, physical health, and psychological health effects of the pandemic could have impacted the delivery and effectiveness of the interventions. Psychological stress was higher during this time [94]; hence, reducing it to “normal prepandemic times” levels was perhaps more challenging, especially in populations who already had high stress before the pandemic, which further compounded it.

It would be of research interest for future studies to undertake functional magnetic resonance imaging scans to evaluate whether the mindfulness-based interventions lead to actual changes in the brain [95], which could complement subjective self-report measures of changes in mindfulness.

Third, we aimed to determine what KT strategies were used and whether the interventions improved knowledge regarding self-care, mental health, and resilience. We found that there is a gap in the literature when it comes to KT and knowledge dissemination in positive psychology interventions for mental health to youth. Only 7% (3/41) of the studies actually assessed either knowledge (1/41, 2%) or self-efficacy for managing mental health in youth. To understand whether participants actually acquired new knowledge and whether it was disseminated properly, future studies need to measure knowledge levels of positive psychological techniques, including mindfulness, and overall knowledge of mental health care and self-care. It is also important to evaluate self-efficacy for mental health care, and only 4% (2/41) studies examined this. Without understanding whether participants gained knowledge and have perceptions of being capable of taking care of their mental health, the outcomes of these studies are difficult to interpret. Self-efficacy has been previously linked to behavior change [96], highlighting its pertinence to self-care behaviors regarding mental health. Knowledge has been previously found to increase self-help behaviors and awareness of mental health problems in young adults [40]. In addition, by measuring improved knowledge, clinicians can be reassured that knowledge acquisition of new mental health techniques and self-care behaviors assists patients.

Finally, few studies examined knowledge acquired in relation to mental health self-care of mental health literacy. However, it is important to note that a recent systematic review and meta-analysis found that higher levels of mental health self-efficacy specifically do not always lead to behavior change involving help-seeking behavior, and barriers regarding stigma remain [97].

In addition to positive psychology for coping during the pandemic, there are other self-care lifestyle behavioral factors that children and teenagers may modify to improve their mental health. For example, research from the All Our Families cohort in Canada found that improved sleep and reduced screen time were both protective for depression and anxiety in children [98-100]. Research has also found that physical activity is protective of mental health in youth [101]. Thus, interventions and knowledge dissemination efforts may benefit from combined behavioral lifestyle and resilience coping strategies to target child and youth mental health.

Recommendations and Future Areas of Research and Pandemic Preparedness

We recommend integrating the concept of flourishing, positive psychology, and evidence-based mindfulness programs (eg, MBSR) into existing KT programs. This would involve a unified model of knowledge dissemination and implementation, catered to key stakeholders and mental health first aid training providers. Future studies should also measure knowledge levels of self-care behaviors, including mindfulness or general meditative practice, resilience coping skills, mental health self-care knowledge, knowledge of mental health management, and self-efficacy. Ideally, they should combine resilience-building skills with lifestyle behavioral factors (eg, sleep, physical activity, and screen time modifications). Future studies could consider developing a KT tool that will provide children, teenagers, and their families with useful resources on how to build resilience, meditate, and change their lifestyle behaviors to promote mental health.

Finally, future research should further examine the specific barriers related to implementing these interventions during the pandemic to better prepare for a future pandemic. Nevertheless, it is encouraging to note that most studies successfully implemented their interventions using digital media, something that is more accessible during pandemic-related restrictions and lockdowns. Qualitative research with stakeholders, including the young adult participants, could provide a deeper insight into specific facilitators and barriers experienced during the pandemic, which could help with improving the interventions and future pandemic preparedness.

Limitations

A limitation of this review is that only 1 reviewer screened the articles due to resource limitations. Ideally, there should be 2 reviewers who screen articles in scoping reviews, reducing bias in selection and in correctly identifying all sources, which makes this more of a narrative literature review. This study is also limited by resources, whereby we accessed free, publicly available articles, which limited the number of databases that were accessed to 3. There is always a possibility that there were more studies that were not included. However, one reviewer redid the search in July 2024 to make sure that no additional studies were missed in the existing databases that were searched.

In addition, we included pretest-posttest 1-arm study designs and did not restrict the inclusion to only RCTs. However, our goal was not to undertake a meta-analysis but to broadly understand what types of interventions were undertaken during the pandemic, considering that randomization was not always possible during the youth mental health crisis throughout the pandemic.

Nevertheless, there are several strengths to this review, including the fact that it comprehensively captured a diverse range of psychological interventions during the pandemic period. There is a possibility that there are more articles that were overlooked given the resource limitations, but this review shows a comprehensive overview of the patterns and types of studies with their common findings during the global COVID-19 pandemic.

Conclusions

We aimed to review what types of positive psychological interventions or positive psychology–related (with derivatives of positive psychology, such as gratitude, positive emotions, and acceptance) interventions were developed during the global youth mental health crisis of the COVID-19 pandemic to meet the mental health needs of youth during this time. We identified 41 psychological interventions that were undertaken in youth during the pandemic. The studies had mixed findings, but overall, the ones that targeted several positive psychology elements, had clearly defined intervention content, or used evidence-based mindfulness programs had greater effectiveness. The reasons why some mindfulness-based interventions had mixed results during the pandemic are not entirely clear. Finally, there is a gap in the knowledge dissemination and uptake literature, whereby most studies did not assess mental health knowledge; mental health management knowledge; self-efficacy for managing mental health problems; or knowledge levels and self-efficacy for practicing positive psychological techniques, including mindfulness. Future studies should measure knowledge and self-efficacy as part of a KT strategy to promote youth mental health, but they should also consider barriers.

Abstract

Background: Parenting interventions are crucial for promoting family well-being, reducing violence against children, and improving child development outcomes; however, scaling these programs remains a challenge. Prior reviews have characterized the feasibility, acceptability, and effectiveness of other more robust forms of digital parenting interventions (eg, via the web, mobile apps, and videoconferencing). Recently, chatbot technology has emerged as a possible mode for adapting and delivering parenting programs to larger populations (eg, Parenting for Lifelong Health, Incredible Years, and Triple P Parenting).

Objective: This study aims to review the evidence of using chatbots to deliver parenting interventions and assess the feasibility of implementation, acceptability of these interventions, and preliminary outcomes.

Methods: This review conducted a comprehensive search of databases, including Web of Science, MEDLINE, Scopus, ProQuest, and Cochrane Central Register of Controlled Trials. Cochrane Handbook for Systematic Review of Interventions and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines were used to conduct the search. Eligible studies targeted parents of children aged 0 to 18 years; used chatbots via digital platforms, such as the internet, mobile apps, or SMS text messaging; and targeted improving family well-being through parenting. Implementation measures, acceptability, and any reported preliminary measures of effectiveness were included.

Results: Of the 1766 initial results, 10 studies met the inclusion criteria. The included studies, primarily conducted in high-income countries (8/10, 80%), demonstrated a high mean retention rate (72.8%) and reported high acceptability (10/10, 100%). However, significant heterogeneity in interventions, measurement methods, and study quality necessitate cautious interpretation. Reporting bias, lack of clarity in the operationalization of engagement measures, and platform limitations were identified as limiting factors in interpreting findings.

Conclusions: This is the first study to review the implementation feasibility and acceptability of chatbots for delivering parenting programs. While preliminary evidence suggests that chatbots can be used to deliver parenting programs, further research, standardization of reporting, and scaling up of effectiveness testing are critical to harness the full benefits of chatbots for promoting family well-being.

KEYWORDS

chatbot; parenting intervention; feasibility; acceptability; systematic review; implementation

Introduction

Background

Parenting, even in ideal conditions, is a stressful and challenging experience that can manifest in a variety of ways, such as emotional distance from the child, exhaustion in the parental role, decrease in self-efficacy, and loss of a sense of accomplishment as a parent [1]. Parental mental health issues can significantly impact the behavioral outcomes of children, particularly depression and anxiety [2,3]. Thus, finding cost-efficient and scalable approaches to improve parenting skills, reduce parental stress, and support healthy child development is critical to promoting family well-being. In low- and middle-income countries (LMICs), the effects of poverty are exacerbated by existing public health emergencies such as humanitarian crises, displacement, and poor mental health care [4]. These emergencies are associated with increases in violence against children which, in turn, is associated with poor outcomes such as behavioral problems, intimate partner violence, and low cognitive stimulation [4]. Preventing and reducing child maltreatment and its negative developmental outcomes are also linked to the United Nations Sustainable Development Goals (eg, 16.2: “End abuse, exploitation, trafficking and all forms of violence against and torture of children” and 1.3: “Implement nationally appropriate social protection systems and measures for all, including floors, and by 2030 achieve substantial coverage of the poor and the vulnerable”) [5]. Global emergencies such as pandemics, climate change–related natural disasters, and conflict-related displacement have only further highlighted the increasing need to provide support to families coping with stress and promoting a positive child-parent relationship.

Parenting Programs

Parenting programs (also “parenting skills training”) are interventions that aim to improve parenting skills and support parents in acquiring knowledge and or skills to improve the health and well-being of children, including improving the parent-child relationship [6]. These programs, often conducted in group settings, can have a range of theoretical underpinnings and are typically manualized. They are flexible in length, typically ranging 8 to 12 weeks, and can be delivered in a variety of community settings by trained facilitators or subject matter experts [7]. Delivery components typically include (1) presentation of new information (eg, a framework for communicating with the child during an argument), (2) introduction of exercises and opportunities for guided practice (eg, structured scenarios with role-playing), (3) facilitated group discussion, (4) home assignments to apply learned skills with children, and (5) opportunities to provide feedback and discuss home assignments [8].

Programs can be designed for parents individually, as couples (if applicable), with children or adolescents present, or without. Typically, these programs aim to achieve a combination of (1) *educating* parents by providing new information, (2) shifting *attitudes* about parenting practices, and (3) changing the *behavior* of parents [9].

There is extensive evidence to suggest that parenting programs can increase positive parenting skills, improve the parent-child relationship, reduce the use of harsh discipline, and improve child behavioral problems [5]. Programs have been specifically designed for resource-limited settings [10,11], and some can be effectively integrated with other public initiatives such as cash transfer programs [12]. Programs such as Incredible Years, Triple P, Parent-Child Interaction Therapy, Parent Management Training Oregon, Strengthening Families, and Parenting for Lifelong Health have demonstrated to have shown positive outcomes and, in some cases, long-lasting effects [5]. The effectiveness of parenting programs has led to international promotion and scale-up with the support of organizations such as the United Nations International Children’s Emergency Fund and the World Health Organization [13]. Effective scale-up of parenting programs may also thus create a delivery pipeline for other related interventions, such as parental or child-specific mental health interventions, gender-based violence reduction interventions, or integration with other public health initiatives.

Digital Behavior Change Interventions

Digital behavior change interventions (DBCIs), also referred to as behavioral intervention technology-based interventions, are interventions that use technology to support and promote healthy behaviors [14]. These may include interventions supported or delivered via a range of technologies such as websites, mobile apps, software, sensors, or hardware devices to change emotions, behaviors, or cognitions [15,16]. DBCIs can be used to increase the reach of in-person social interventions, particularly to populations that lack access to in-person programs or where in-person services are unavailable. DBCIs can be *guided*, which includes a significant in-person, synchronous component to support implementation, such as an internet-based program for reducing anxiety, which also includes regular low-touch support from a therapist or peer support [17]. They can also be *self-guided*, in which the intervention is administered completely digitally and can be completed asynchronously, similar to a manualized workbook-driven intervention [18,19]. DBCIs are often used in health settings [20-22].

Chatbots

Digital conversational agents, or “chatbots,” are a type of self-guided DBCI. Chatbots respond to written and spoken language with text or spoken language, which can be prewritten or generated by artificial intelligence. Their capability is far-ranging; the simplest implementation of chatbots uses predefined algorithms where specific outputs are triggered by specific inputs from the user, while a highly sophisticated chatbot may use an artificial intelligence model to generate novel responses and learn from a user’s behavior to personalize responses over time [23]. Chatbots can be particularly useful for emulating human interaction and have been used successfully in physical health care, mental health care, and educational settings. In some cases, chatbots have demonstrated levels of trust with study participants similar to in-person interventions with physicians, therapists, or educators [19,24,25]. Chatbots can also be combined with other intervention modalities to support sustained engagement or on-demand, interactive access to intervention content [26,27].

Chatbot-based implementations of parenting programs can be delivered via internet-based messaging platforms (eg, Facebook Messenger, WhatsApp, and Signal); mobile apps that embed the chatbot within; and SMS text messaging, which does not require a mobile internet connection, is capable of sending multimedia content, and can be accessed at any time. SMS text messaging–based support messages have already been used to support in-person parenting programs in LMICs [28]. Their automated and highly customizable design makes the mode of delivery potentially useful for intervention settings that lack access to in-person services, require flexibility in participating in an intervention (such as a parenting program), or prefer a lower-intensity form of intervention. SMS text messaging delivery also has cost implications for providers, making them less feasible for wide-scale use in low-resource settings without government or telecom provider partnerships. With the introduction of powerful large language models capable of replicating highly accurate syntax and tone, there is a newfound need to understand the extent to which chatbot technology can be a suitable method for delivering interventions to populations experiencing barriers to in-person implementations.

Past reviews have examined the feasibility, acceptability, intervention characteristics, and effectiveness of digital parenting interventions, particularly for infants and young children [29,30]. These reviews have focused primarily on more complex digital modalities that include internet-based multimedia content, digitally supported interventions with primary in-person components, and technology that connects parents with in-person support [31,32]. Little work has focused on self-guided digital interventions such as chatbots. Preliminary pilots and trials of parenting programs delivered via chatbots have begun to be published, though, to the best of our knowledge, no synthesis has examined whether the evidence indicates that chatbots are a feasible and acceptable method for delivering parenting programs. Answering this question is critical for guiding future research in scaling up chatbot-based parenting programs. It is essential to evaluate the feasibility and acceptability of chatbot-based parenting programs as a whole, rather than focusing solely on individual studies. Understanding these aspects is crucial for determining the viability of this technology as a route for intervention delivery as well as developing it further. The aim of this study is to systematically review the existing studies reporting on the feasibility and acceptability of chatbot-delivered parenting interventions. We aim to describe the various types of parenting chatbots, explore the methods used to assess the feasibility and acceptability of chatbot-based parenting interventions, and evaluate the quality of evidence supporting this technology.

Methods

Reporting Guidelines

The design of this study followed the *Cochrane Handbook for Systematic Review of Interventions* [33] and the updated 2020 PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for conducting and reporting systematic reviews [34].

Inclusion Criteria

Studies were included if they targeted parents of children aged 0 to 18 years. The intervention needed to report an explicit focus on improving overall psychosocial well-being of family via advances in parenting, including reducing negative phenomena such as violence against children, abuse of children, and harsh parenting practices. The intervention needed to be delivered in the form an interactive conversational agent ("chatbot") but could do so through any digital modality (internet based, mobile app, or SMS text messaging). For example, a website delivering a parenting skills training program to reduce child behavior problems and improve the parent-child relationship would only be included if the content was delivered via an identifiable, automated conversational agent within the website. Chatbots with and without artificial intelligence models for generating responses were included. In addition, the chatbot needed to be the primary component of intervention delivery, rather than as an add-on for monitoring or support purposes; studies with in-person components outside of onboarding were excluded. Intervention content could vary but needed to aim mainly and explicitly to improve parenting skills, including knowledge of or attitudes about parenting practices, self-care as it relates to parenting, the parent-child relationship, and preparing for parenting. Interventions that included lifestyle-related interventions were only included if the intervention content targeted changes in parental knowledge, attitudes, or behaviors. Studies in English and Spanish were included. No time restrictions were imposed on articles, though it was noted that studies before the 1990s would likely not meet the criteria, as this predated the internet. Data extracted from peer-reviewed published articles and gray literature, such as reports of ongoing studies, protocols, conference proceedings, and dissertations, were included to identify full reports of studies. Any study design meeting the abovementioned criteria was included to characterize this literature as broadly as possible.

Exclusion Criteria

Solely qualitative articles were excluded. Studies with in-person components outside of onboarding were excluded. Studies that did not explicitly focus on improving overall psychosocial well-being of family via advances in parenting, including reducing negative phenomena such as violence against children, abuse of children, and harsh parenting practices, were excluded. Articles that did not feature an interactive conversational agent ("chatbot") or were delivered via nondigital modalities were excluded. Studies where the chatbot was not the primary component of intervention delivery were also excluded. Articles in languages other than English and Spanish were excluded. Studies with no clear target on improving parenting skills, including knowledge of or attitudes about parenting practices, self-care as it relates to parenting, the parent-child relationship, and preparing for parenting, were not considered. Interventions that included lifestyle-related interventions but did not target changes in parental knowledge, attitudes, or behaviors were excluded.

Primary and Secondary Outcomes

Primary outcomes of this review were measures of implementation, acceptability, and secondary measures of family well-being as measured by changes in parental knowledge, attitudes, behaviors, and psychological well-being (including symptoms of anxiety or depression) as well as child outcomes, such as reduction of behavioral or emotional problems. If multiple measures of implementation and acceptability were reported, these were categorized into primary and secondary measures with respect to their reporting within the study.

Due to the nascency of the literature, criteria for inclusion were developed to maximize *sensitivity* across population and outcome descriptors, while also maximizing *specificity* with the type of intervention. Nonrandomized studies, including feasibility and acceptability studies, as well as quasi-experimental studies, were included alongside randomized trials. Further details regarding the inclusion and exclusion criteria can be found in Textbox 1.

Textbox 1. Intervention inclusion and exclusion criteria.

Inclusion criteria

- Intervention targets parents of children aged 0 to 18 years
- Intervention aims to improve the overall psychosocial well-being of family via changes in parenting, including reducing negative phenomena, such as violence against children
- Intervention is delivered via a digital, interactive conversational agent (“chatbot”)
- Intervention primarily and explicitly aims to improve parenting skills, including enhancing knowledge and attitudes

Exclusion criteria

- Intervention is delivered to children (but may have parental involvement)
- Intervention aims to improve outcomes tangentially related to well-being of family, including health reminders, disease prevention, weight management, and smoking cessation
- Intervention does not contain a digital, interactive conversational agent (websites, SMS text messages with no interactive component, and mobile apps with no interactive component)
- Intervention uses a digital chatbot as an add-on for monitoring or support purposes, rather than as a primary delivery mechanism
- Intervention delivers skills that are tangentially related to good parenting (child weight management, reducing unhealthy food intake, vaccine uptake, and health reminders) but are not parenting skills (mental health interventions)

Search Strategy

The search was conducted in August 2023. Web of Science (Science Citation Index, Social Sciences Citation Index, Conference Proceedings Citation Index, and Emerging Sources Citation Index), MEDLINE, Scopus, ProQuest (Social Sciences Collection), and Cochrane Central Register of Controlled Trials were searched. All database searches were exported to Covidence systematic review software [35] for deduplication and screening. The search string was developed using the PICO framework (Population, Intervention, Comparator, Outcomes), shown in Textbox 1. A full search string can be found in Multimedia Appendix 1.

Study Selection

All stages of the study process, including title and abstract screening, full-text review, data extraction, and quality assessment, were double-screened by MCK and AR. Screeners were blinded until the team met to resolve conflicts. Conflicts not resolved by consensus were advised on by the senior reviewer (FG). Study selection was conducted independently by the main coder (MCK) and a trained coder (AR) by title, abstract, and then full text. Intercoder reliability was maintained at each step of the screening process. The main coder opted to establish reliability at each stage independently to account for the range of considerations associated with each stage [36]. The main coder recruited and trained the second coder by jointly screening 25 (1.4%) of the 1766 included studies. Any questions about inclusion criteria were addressed before independent screening of titles and abstracts. Full-text screening involved joint training and screening of 10 studies. The main coder provided training on data extraction variables, and discussions followed independent coding of a small number of selected studies. Percent agreement was calculated at each stage by comparing agreements to selections. Successful training required ≥90% agreement, exceeding standard practice [36,37]. Any disagreements not resolved by discussion were settled by a third coder. Textbox 1 was used as a reference for screening, and the author and second coder met twice to resolve conflicts identified between screening. All excluded articles were labeled with a reason for exclusion.

Data Extraction

Before extraction, separate articles were selected from the study by Vissenberg et al [38], a different but topically relevant review to practice applying the data extraction template to a similar group of studies. Due to the heterogeneous nature of study design and interventions, a meta-analysis synthesis was not possible. Instead, the features of interest included variable measures of feasibility and acceptability, type of delivery, and income level of intervention setting, and any measures of effectiveness were narratively synthesized.

Primary feasibility outcomes were operationalized as the included study's main reported quantitative metric of engagement, which could vary between studies. Primary acceptability outcomes were operationalized as the included study's main reported quantitative metric of acceptability, and if multiple measures were reported, measures of participants' (1) overall appraisal of the intervention, (2) reported likelihood of using the intervention again, or (3) likelihood of recommending the intervention to someone else were considered primary measures. Secondary feasibility outcome measures were any additional quantitative measures of engagement. Secondary acceptability measures were any additional quantitative or qualitative variables related to participants' experience with the intervention, or (2) or (3), if (1) was reported. Any effectiveness measures reported by each study was also extracted. Reported barriers and facilitators to use, either through free-response items on end point surveys or through participant feedback, were also extracted.

Assessment of Study Quality and Risk of Bias

Studies that met the eligibility criteria were assessed for quality and relevance using the Weight of Evidence (WoE) framework [39]. Each study was scored across three criteria: (1) WoE A: general quality, (2) relevancy of study design to review question, and (3) relevancy of intervention design to review question, to produce (4) an overall WoE score. Each criterion was given a score of 1 ("Low"), 2 ("Moderate"), or 3 ("High"). Criteria (2) and (3) are prespecified in the study by Gough [39]. Full WoE assessment criteria can be found in Table 1. To assess study quality more objectively, the *Standard Quality Assessment Criteria for Evaluating Primary Research Papers from a Variety of Fields* (QualSyst) [40], which is designed for mixed methods, pre-post, and randomized designs, was used to score WoE A. Example items from QualSyst include the following: "Was the research question sufficiently described? (item 1)," "If interventional and blinding of subjects was possible, was it reported? (item 7)," and "Were the outcome measures well-defined and robust to measurement bias? (item 8)." A full list of items is provided in Multimedia Appendix 2.

Table 1. Weight of Evidence assessment rubric.

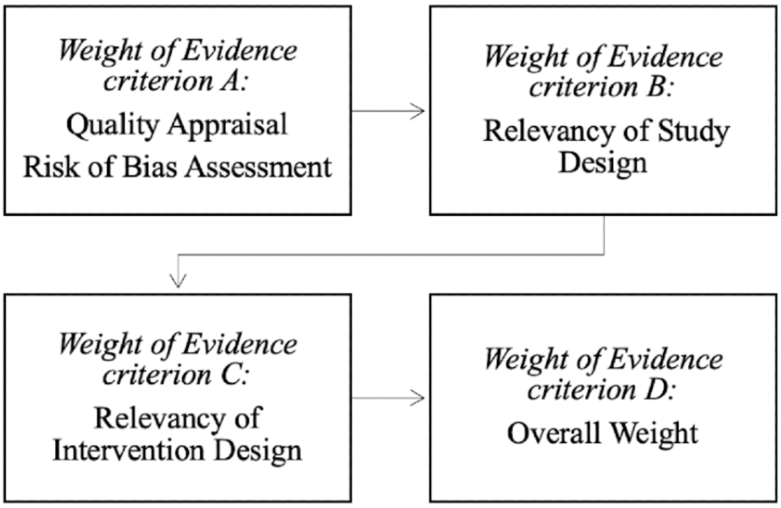
	Criterion A: QualSys[a] quality appraisal tool score	Criterion B: relevancy of study design	Criterion C: relevancy of intervention design	Criterion D: averaged weight (criteria A, B, and C)
Low (=1.00)	0-0.55	• Does not mention feasibility and/or acceptability AND/OR • Makes conclusions about feasibility and acceptability without a clear link to evidence	• <60% of the content delivered is parent skills training OR • Partially automated, but manual components OR • Has an equal number of components that are nondigital	1.00-1.75
Moderate (=2.00)	0.56-0.80	• Mentions feasibility and acceptability measures AND/OR • Measures are not adequate for assessing feasibility and acceptability; makes strong conclusions with mixed evidence	• >60% of content is parent skills training OR • Primarily automated but includes at least 1 manual component OR • Mostly digital, may have some nondigital components	1.76-2.65
High (=3.00)	0.81-1.00	• Explicitly reports feasibility and acceptability measures or effectiveness (if feasibility and acceptability has been established) AND/OR • Measures are adequate, and conclusions about feasibility and acceptability are in line with the evidence provided	• Only delivers parenting training (which may include parenting-specific stress management) AND • Fully automated OR • Fully interactive • Completely digital	2.66-3.00

[a] QualSys: Standard Quality Assessment Criteria for Evaluating Primary Research Papers from a Variety of Fields.

Cut points from QualSyst were used to harmonize scoring between the 2 tools, where a QualSyst score of 0 to 0.55 was translated to a WoE score of 1 ("low"), 0.56 to 0.80 to 2 ("moderate") and 0.81 to 1.00 to 3 ("high").

To assess risk of bias, domains from the Cochrane Risk of Bias in Nonrandomized Studies of Interventions and Risk of Bias Tool version 2 [41,42] were identified and assessed against the 14 criteria in the QualSyst tool. Descriptions of how to assess each domain in the Cochrane Risk of Bias in Nonrandomized Studies of Interventions were used to guide the review process. The quality and risk of bias assessment process is described in Figure 1.

Figure 1. Quality and risk of bias assessment.

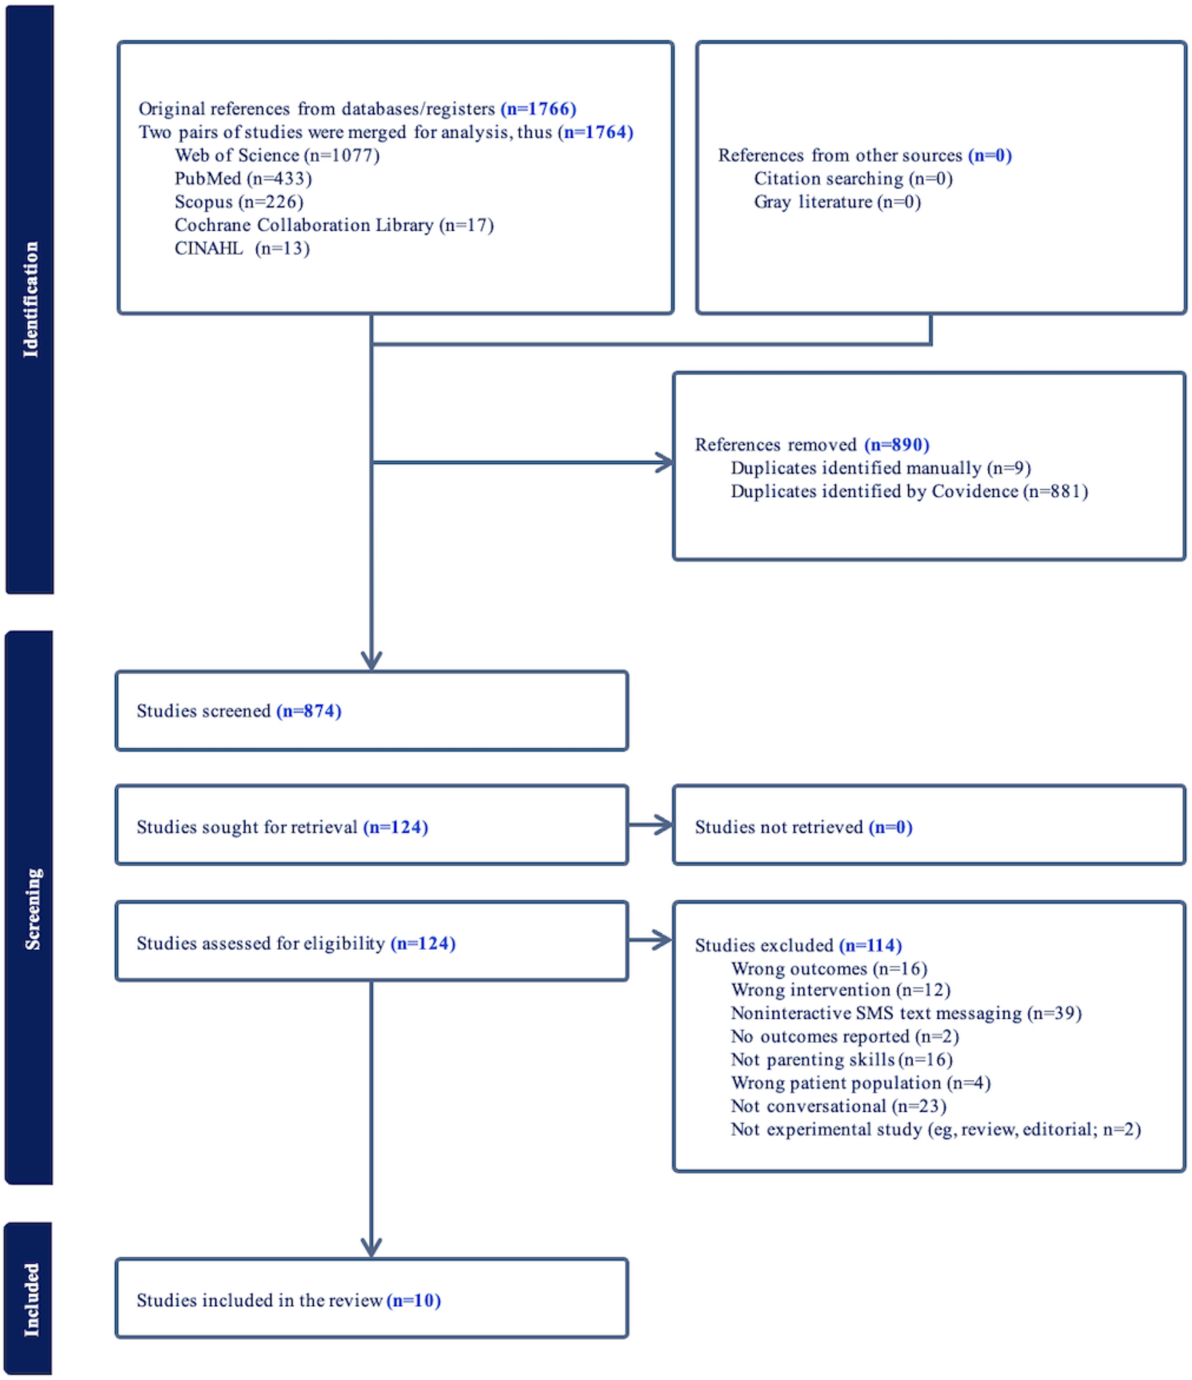


Results

Included Studies

The search yielded 1766 results, and 874 studies remained after deduplication (Figure 2). After title and abstract screening, full text of 124 studies were screened and 114 were excluded, leaving 10 included studies. The most common reasons for exclusion were the intervention being noninteractive (39/114, 34.2%); digital, but not in a conversational messaging format (23/114, 20.1%); did not include parenting-related outcomes (16/114, 14%); and did not deliver parenting skills as a primary component of the intervention (16/114, 14%). The complete list of exclusions can be seen in Figure 2. A total of 4 articles were merged into 2 studies: (1) the studies by Fletcher et al [43,44], due to the 2019 publication describing the development and intervention content and 2020 describing the feasibility study, and (2) the studies by Entenberg et al [45,46], as they report on different, relevant aspects of the same trial.

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) study flow diagram.



Among the 10 studies included, 8 (80%) were conducted in high-income countries—3 (30%) in Australia [43,44,47]; 2 (20%) in Argentina [46,48]; and 1 (10%) each in the United States [49], Taiwan [50], and Singapore [51]. A total of 2 studies were carried out in middle-income countries, with 1 in Brazil [52] and 1 in Peru [53]. The total participant pool across all studies (n=772) was drawn from diverse settings, including inpatient, outpatient, university, and community settings. The studies focused on parents with children spanning various age groups: 3 studies involved parents with infants aged 0 to 3 months [43,44,52], 4 studies targeted parents with children aged 2 to 11 years [46-48,50], 1 study addressed adolescents aged 13 to 18 years alongside the parenting intervention [49], another study included pregnant women and mothers with children aged 0 to 6 years [53], and 1 study focused on prospective parents, evaluating the intervention with men and women of childbearing age who mostly did not have children [51]. A full description of the characteristics of the included studies can be found in Table 2.

Table 2. Sample characteristics of the included studies.

Study, year	Country	Service setting	Income level	Study design	Population	Participant mean age	Method of recruitment	Total number of participants	Intervention length	Theoretical orientation (if stated)	Delivery type
Entenberg et al [45,46], 2023	Argentina	Not included	High-income setting	Randomized controlled trial	Parents in Argentina with at least 1 child aged 2 to 11 years	35.85 (SD 5.77)	Facebook posts and email list advertisements	170 (intervention group: 89; control group: 81)	15 minutes	Incredible Years Parenting Programme; behavior change techniques	Facebook Messenger
Fletcher et al [43], 2017	Australia	Not included	High-income setting	Pilot feasibility and acceptability study	Fathers expecting a child within 6 months or fathers with infants younger than 3 months	33.7 (range 21-59)	Advertisement posters in community centers, through Facebook forums, and at the hospital neonatal intensive care unit via trained staff	46	6 weeks	Psychoeducation, mood monitoring, and awareness	SMS text messaging
Fletcher et al [44], 2020	Australia	Not included	High-income setting	Pilot feasibility and acceptability study (no effectiveness)	Partners of mothers diagnosed with perinatal mental illness	29.3	Partners were invited after clinical interview at regional health centers	23	44 weeks	Psychoeducation, mood monitoring, and awareness	SMS text messaging
Mason et al [49], 2021	United States	Health care clinic	High-income setting	Randomized controlled trial	Parents of adolescents (aged 13 to 18 years) participating in the substance abuse prevention program	Parent mean age not reported	Community partner advertisement	52 (parents); 69 (adolescents)	4 weeks	Behavioral-skill framework (Dishion et al [54])	SMS text messaging
Entenberg et al [48], 2021	Argentina	Not included	High-income setting	Randomized controlled trial	Parents aged ≥18 with at least 1 child aged 2 to 10 years; not seeking psychological treatment	33.3% (n=11) of the participants were aged between 30 and 33 years, 30.3% (n=10) aged between 34 and 37 years, and 36.4% (n=12) were aged ≥38 years	Facebook posts	33	20 minutes	Incredible Years Parenting Programme	Facebook Messenger
Barreto et al [52], 2021	Brazil	Hospital	High-income setting	Intervention development and acceptability evaluation	New mothers aged >18 years with newborns of at least 24 hours old	24.4	Approached by research team in hospital and asked to participate	142	No time limit	Not stated	Within app

Study, year	Country	Service setting	Income level	Study design	Population	Participant mean age	Method of recruitment	Total number of participants	Intervention length	Theoretical orientation (if stated)	Delivery type
Downing et al [47], 2018	Australia	University (for initial onboarding)	High-income setting	Randomized controlled trial	Parents of children aged 2 to 4 years	Intervention group: 36.1 (3.9); control group: 34.1 (3.7)	Snowball method through community outreach and advertising	57 (Intervention group=30, control group =27)	6 weeks	Behavior change (CALO-RE)	Text messaging
Yu et al [50], 2023	Taiwan	Not reported	High-income setting	Intervention development and acceptability evaluation	Parents with childrearing difficulties	NR[a]	NR	58	12 weeks	Behavior change	Within app
Chua et al [51], 2023	Singapore	Tertiary public hospital	High-income setting	Intervention development and acceptability evaluation	Men and women of childbearing age; 10 with no children, single	26.7	Convenience sampling	11	28 weeks	Bandura self-efficacy theory, positive psychology, and psychoeducation	Within app
Jäggi et al [53], 2023	Peru	In home for onboarding and baseline interviews	Low-income setting	Pilot feasibility and acceptability study	Pregnant women and mothers with children aged 0 to 6 years	29	Convenience sampling	180	20 weeks	NR	Facebook Messenger

[a] NR: not reported.

Study Design and Intervention Structure

A total of 3 studies were randomized, 4 were nonrandomized evaluations of intervention feasibility and acceptability, and 3 were intervention development reports that included preliminary surveys of acceptability. A full description of the characteristics of included studies can be found in Table 2. Participants were recruited by diverse methods, with advertisements on social media in parent groups being the most common. Sample sizes ranged from 11 to 170 participants. The 10 studies evaluated 8 distinct interventions delivered via SMS text messaging (4/10, 40%), Facebook Messenger (3/10, 30%), and a mobile app (3/10, 30%). While all the intervention aims included improving parenting skills, specific content varied and included positive praise, improving the parent-infant relationship, reducing parental stress, improving communication skills, and improving parental confidence. Intervention duration ranged from 15 minutes to 11 months, with 1 intervention [52] allowing parents to use the chatbot as long as needed with a prespecified end time to the pilot or experimental period. Theoretical orientation was not clearly reported in most cases, but behavior change (4/10, 40%) and psychoeducation (3/10, 30%) were the most reported.

Factors Related to Implementation and Acceptability

Interactivity

Interactivity varied between interventions and was difficult to compare. One dimension of interactivity is the ability of the chatbot to respond realistically to queries or responses from participants. For example, the chatbot assessed by Entenberg et al [45,46,48] could be considered highly interactive, as they were supported by an artificial intelligence model that produced realistic speech-like text and could respond to participant messages that may have not been predicted by intervention developers. The other interventions were automated but used prewritten text message flows. As a result, intervention developers either predicted possible responses that the chatbot could respond to, or, more often, had specific response options embedded in messages to cue participants. Another dimension of interactivity is the extent to which content requires a response from participants. Generally, while some included studies gave examples of messages or templates, no studies had content flows accessible to independently assess the types of responses required from participants to interact with the content. Barreto et al [52], Entenberg et al [45,46,48], and Mason et al [49] delivered content that was both conversational and required complex textual responses to prompts from the chatbot, whereas Fletcher et al [43,44] and Downing et al [47] used templated messages that embedded cued responses to participants in messages and did not require complex textual inputs from the participant to continue. The latter studies also sent messages less frequently, and some messages did not require responses from participants. Considerable variation in both the degree of interactivity and the theoretical orientation of interventions, coupled with differences in their duration, poses a significant challenge in assessing the influence of interactivity on participant engagement.

Length of the Intervention

Intervention length also varied substantially, which can be attributed in part to variable approaches for the intended aim of the intervention for the participant. The studies by Barreto et al [52] and Fletcher et al [43], for example, were explicitly designed to serve as an on-demand source of information for parents to access or be prompted by over a long period, as evidenced by the substantially longer intervention period (note: the study by Barreto et al [52] does not specify a maximum length of intervention). In contrast, the intervention tested by Entenberg et al [45,46,48] was brief, lasting <30 minutes, and focused on a specific parenting skill. These interventions represent 2 extremes in terms of length within the review and demonstrate the relationship between purpose and duration. This relationship is also evident when examining the relative interactivity of the chatbot interventions. For instance, the intervention by Entenberg et al [45,46,48] involved a brief but highly detailed interactive exchange between the chatbot and the participant. In contrast, interventions by Mason et al [49] and Downing et al [47] were lighter touch, with messages requiring shorter responses that were often limited to “Yes,” “No,” or other affirmative responses.

Delivery Mode Informs Measurement Limitations

The considerable heterogeneity in measuring feasibility outcomes, such as retention, engagement, and completion, can in part be attributed to the platforms the chatbots were delivered on. For example, Barreto et al [52] delivered the chatbot in a downloadable mobile app, where it was possible to measure engagement characteristics such as mean length of engagement, which menus were accessed, and which information was accessed. Alternatively, interventions delivered via SMS text messaging, where that level of use data is not available, primarily measured engagement characteristics by number of responses or engagement with external links. Interventions delivered via Facebook Messenger reported less engagement-related data as via mobile app, but more than SMS text messaging–based interventions. Thus, a relationship between *how* the intervention is delivered and *what* engagement data can be collected exists and can affect feasibility reporting.

Quality Assessment

Overview

The 10 studies included in the review were evaluated across three criteria: (1) quality of study and risk of bias, (2) relevancy of study design to review question, (3) relevancy of intervention to review question, using a WoE framework (refer to Table 1 and Multimedia Appendix 2 for evaluation criteria). A full list of quality assessment ratings may be found in Multimedia Appendix 3.

Individual Quality and Risk of Bias

Less than of the included studies were rated as high quality with a low overall risk of bias (4/10, 40%) or moderate quality with a low-to-moderate overall risk of bias (1/10, 10%), and half were rated as low quality with a high potential risk of bias (5/10, 50%). The most common reasons for lower ratings included unclear outcome measures, a lack of control for potential confounding variables, or unclear or inadequate analysis.

Relevancy of the Study Design

Most studies had highly relevant study designs (6/10, 60%). The most common reasons for studies being rated as “low” in relevancy of study design was due to not primarily measuring feasibility and for making conclusions about feasibility or acceptability without clear links to reported evidence.

Relevancy of the Intervention

Most studies had moderate (6/10, 60%) or highly relevant interventions (3/10, 30%). The most common reason for lower ratings were additional content unrelated to parenting skills rather than core content being unrelated to parenting skills.

Overall WoE

In total, 30% (3/10) of the studies demonstrated “high” quality, indicating robust methodology and high relevance to the research question. Of the 10 studies, 3 (30%) were rated as “low” quality, indicating issues with reporting and measurement. For example, Barreto et al [52] measured participant engagement by the mean number of access events but failed to clarify how this was operationalized or how confounding factors such as repeated access within a short period were controlled in the study. Overall, the evidence was moderately weighted (mean 2.36, SD 0.65), with 3 (30%) of the 10 studies receiving a high-weighted evidence rating, 4 (40%) studies receiving a moderate-weighted evidence rating, and 3 (30%) studies receiving a low-weighted evidence rating. This indicates that the current evidence moderately supports the feasibility and acceptability of chatbot-delivered parenting programs, but substantial development in both the evidence and reporting of findings is needed.

Feasibility and Acceptability

Primary Implementation Measures

Retention was the most reported primary measure of implementation (8/10, 80%), though the operationalization of the measure varied between the 8 studies. A full description of the feasibility, acceptability, and preliminary outcomes can be found in Table 3. One study [52] reported the mean number of times the chatbot was accessed as a primary implementation measure, and 1 study [51] did not report any implementation measures. A total of 3 studies measured retention by participants fully completing the program, 2 studies [43,44] measured retention by participants who did not opt out of the intervention by the end of the evaluation period, 2 studies [47,50] measured retention by the number of participants who completed the postintervention survey, and 1 study measured retention by the number of active users at the end of the prespecified intervention evaluation period [53]. A weighted mean retention rate was calculated as 72.8% retention across studies, though this reflects retention rates reported by studies pooled together, without adjusting to compare similar measures to one another.

Table 3. Feasibility, acceptability, and effectiveness outcomes of the included studies.

Study, year	Total number of participants	Primary feasibility measure	Score (primary feasibility)	Secondary feasibility measure	Score (secondary feasibility)	Primary acceptability measure	Score (primary acceptability measure)	Secondary acceptability measures	Score (secondary acceptability)	Effectiveness outcome measure	Score (effectiveness)	Recommendation for use
Entenberg et al [45,46], 2023	170 (Intervention group: 89, control group: 81)	Retention	Dropout: 29% (26); completed intervention: 66% (59); completed follow-up: 28% (25)	Completion, dropout by skill and number of messages	Intervention group: 66.3% (59/81), skill 1: 17.98% (16), skill 2: 6.86% (5), skill 3: 7.35% (5), skill 4: 1.58% (1), and skill 5: 4.83% (3); number of messages: 49.8 (SD 1.53; range 20-80)	Satisfaction (1-5); Net Promoter Score (1-5)	Satisfaction: 4.19 (0.79); Net Promoter Score: 4.63 (0.66)	Survey (Likert 1-5): ease of use, comfort, absence of technical problems, interactivity, and usefulness in everyday life	Survey (Likert 1-5): ease of use: 4.66 (0.73) comfort: 4.76 (0.46) absence of technical problems: 4.69 (0.59) interactivity: 4.51 (0.77) usefulness in everyday life: 4.75 (0.54)	Self-efficacy, disruptive behavior	Mean 0.21 (SD 0.59); mean 0.37 (SD 0.96)	Recommended
Fletcher et al [43], 2017	46	Retention (*measured by number ofparticipants who did not explicitly exit the intervention*)	87%	Accessing embedded links	Embedded links: most frequently clicked= 14/65 (22%); mood tracker: 24 (52%) responded ≥1 times	Recommend to others (Likert 1-5)	4.6	Structured phone interview (11 Likert scale questions): usefulness of intervention	4.32 (0.58)	NR[a]	NR	Recommended
Fletcher et al [44], 2020	23	Retention (*measured by use of embedded links and responses to the mood tracker*)	95.6% (22/23)	Embedded links: most frequently clicked= 8/23 (34.8%); mood tracker link, no response: 6/23 (26.1%)	1 (4.3%)	Likert Survey: "The messages helped me to develop a strong relationship with my new child."	80%—agree or strongly agree	Likert survey: "The mood tracker messages, where I could respond to questions about how I was feeling, were useful for me"	43.8% (7)—agree or strongly agree	NR	NR	Recommended

Study, year	Total number of participants	Primary feasibility measure	Score (primary feasibility)	Secondary feasibility measure	Score (secondary feasibility)	Primary acceptability measure	Score (primary acceptability measure)	Secondary acceptability measures	Score (secondary acceptability)	Effectiveness outcome measure	Score (effectiveness)	Recommendation for use
Mason et al [49], 2021	52 (parents); 69 (adolescents)	Retention *(measured by number of participants who completed the intervention)*	98%	Response rate	93%	Helpfulness (measured at postintervention survey)	78%	Self-report: (1) satisfaction with no of texts and (2) use of skills	(1) 96% and (2) 91%	Parenting Practices Scale	0.34, SE 0.27, *P*=.21	Recommended
Entenberg et al [48], 2021	33	Retention *(measured by number of participants who completed the intervention)*	78.8% (26)	Number of messages sent	54.24 (SD 13.05)	Net Promoter Score (1-10)	7.44 (SD 2.31)	NR	NR	NR	NR	Recommended
Barreto et al [52], 2021	142	Mean number of times accessing chatbot	2	Length of conversation	27 seconds	Likert survey of experience and attitudes: "I liked using the GCBMB."	96.4% "Totally agree" (137)	NR	NR	NR	NR	Recommended
Downing et al [47], 2018	57 (intervention group: 30, control group: 27)	Retention *(measured by number of participants who completed the intervention)*	Intervention group: 63%, control group: 70%	Number of replies to goal monitoring messages	83.3% (145/173)	Self-report use	95% (19/20) report reading at least 9 of 12 messages	NR	NR	Children's sitting time (activPAL)	−30.6 minute/day	Recommended
Yu et al [50], 2023	58	Retention *(measured by the completion rate of the postintervention survey)*	51.7%	NR	NR	Chatbot usefulness for problem-solving *(Self-report questionnaire)*	>4.5/5 on all 6 items	NR	NR	NR	NR	Recommended
Chua et al [51], 2023	11	NR	NR	NR	NR	User acceptability testing survey, *(items 4-9; 1-7 Likert scale)*	Language appropriateness: mean=6.25; perceived friendliness: mean=5.9; enjoyability of use: mean=5.7	NR	NR	NR	NR	Recommended

Study, year	Total number of participants	Primary feasibility measure	Score (primary feasibility)	Secondary feasibility measure	Score (secondary feasibility)	Primary acceptability measure	Score (primary acceptability measure)	Secondary acceptability measures	Score (secondary acceptability)	Effectiveness outcome measure	Score (effectiveness)	Recommendation for use
Jäggi et al, [53], 2023	180	Retention *(measured by the number of active users at the end of the intervention period)*	41.7%	Intervention connectivity coverage	Urban (100%, 5/5), rural (22%, 10/44)	Chatbot usefulness (*Likert-like scale)*	87% rated "useful" to "very useful"; mean 4.37/5 (SD 1.00)	NR	NR	NR	NR	Recommended

[a] NR: not reported.

Secondary Implementation Measures

A total of 7 studies reported secondary measures of implementation. Fletcher et al [43,44] reported engagement as measured by the number of participants who accessed embedded links within the chatbot's mood tracker at least once (24/46, 52% and 8/23, 26%, respectively). In addition to overall retention, Entenberg et al [45,46] assessed retention by intervention component, reporting a 79% (26/33) retention rate after the first of 5 components, as well as the number of messages sent between the chatbot and participant (mean 49.8, SD 1.53). Entenberg et al [48] also reported the number of messages sent (mean 54.24, SD 13.05). Similarly, Barreto et al [52] measured mean duration of chatbot-participant interaction (27.0 seconds). Mason et al [49] measured engagement by the percentage of participants who responded to the 3-month follow-up survey (48/52, 92%). Jäggi et al [53] was the only study that reported a non–engagement-related secondary measure of implementation examining intervention connectivity coverage for the chatbot across 49 test sites (urban: 5/5, 100%; rural: 10/44, 22%).

Primary Acceptability Measures

All 10 studies used self-report data to assess acceptability. The most common measure was a Likert-like scale with an item asking participants to indicate their overall attitudes toward the chatbot. Items varied in focus. Fletcher et al [44] asked participants to indicate the extent to which they agreed that "The messages helped me to develop a strong relationship with my child," whereas Barreto et al [52] asked participants to rate the extent to which they agreed with the statement "I liked using the chatbot." A total of 2 studies [46,48] assessed the likelihood of recommending the chatbot to a friend, as measured by the Net Promoter Score [55]. The study by Downing et al [47] was the only study that reported self-reported use as secondary measure of acceptability, as indicated by the percentage of participants reported reading at least 9 (95%) of 12 messages. While a weighted mean was not calculated due to the considerable heterogeneity in survey items, all studies reported high acceptability across their chosen measures.

Secondary Acceptability Measures

A total of 5 studies reported secondary measures of acceptability. All 5 studies [43,44,46,48,49] used quantitative self-report surveys to identify participant attitudes about ease of use, perceived usefulness, and comfort with the chatbot. Similar to primary acceptability and primary feasibility measures, there was considerable heterogeneity, though all studies reported high acceptability across additional measures. Entenberg et al [45,46] reported high ease of use (mean 4.66/5.0, SD 0.73), Fletcher et al [43,44] found high perceived usefulness (mean 4.32/5.0, SD 0.58; approximately 43.8% of participants agreed that the mood tracking interactive component was helpful), and Mason et al [49] found that 91% of the participants reported using skills learned from the chatbot within 3 months after the program.

Preliminary Effectiveness

A total of 3 studies reported effectiveness outcomes. Entenberg et al [45,46] observed a small positive effect of the intervention on mean parental self-efficacy (Cohen d=0.36; mean 0.21, SD 0.59) and a moderate decrease in disruptive behavior (Cohen d=0.39; mean 0.37, SD 0.96), though neither reached statistical significance. Mason et al [49] also identified a small positive effect on parenting practices, measured by the Parenting Practices Scale (Gorman-Smith et al [56]; $F_{1,150}$=0.57), but it did not achieve statistical significance (P=.45). Downing et al [47] did not report effectiveness outcomes related to parenting but focused on child sedentary behavior, a primary outcome related to the intervention aim. They found a significant positive effect of the intervention, indicating a decrease in the average number of minutes children spent sedentary per day (adjusted mean –22.3 min/day; 95% CI –80.8 to 36.3), suggesting preliminary effectiveness.

Barriers and Facilitators to Use

A total of 5 studies reported on barriers and facilitators to use within the chatbot interventions [43,46-48,53]. All studies collected data through structured interviewing and Likert-like surveys. Parental busyness, impersonal and inflexible response from chatbots, technical problems, and repetitive or unengaging information were reported as barriers to use. Participants solely owning the device used for the intervention, technical support call buttons, encouraging messages, communication style and advice perceived as helpful, goal setting, and easy-to-understand messages were reported as facilitators for use. While other studies discussed potential barriers and facilitators, none reported formal methods for assessing these within the study.

Discussion

Principal Findings

This is the first study to review the implementation and acceptability characteristics of chatbot-delivered parenting interventions. Findings suggest that chatbots can be a feasible and acceptable method for delivery, but further research is required to assess whether engagement with the technology can be sustained as well as effectiveness compared to other digital parenting interventions. We identified an average retention rate of 72.8% across included studies. While all included studies individually conclude that chatbot interventions are implementable and acceptable, substantial development is needed in the standardization of definitions, measurements, and reporting. In addition, there is some evidence supporting moderate levels of implementation feasibility and acceptability of these interventions in high-income countries. However, there is limited evidence in middle-income countries and none in low-income countries. Implementation, primarily measured by retention, appeared to be high across included studies, as did retention as measured by program completion. Acceptability, primarily measured by self-report items about attitudes toward satisfaction and usefulness, was also considerably high in all included studies.

In addition, this review found that the delivery of parenting chatbots cited in included studies encountered external barriers such as parental busyness and internal barriers such as inflexible responses from the chatbots, technical problems, or repetitive information. Generally, chatbots were more acceptable when they used encouraging messages, easy-to-understand content, and content that was perceived as helpful or involved incremental goal setting. However, this review did not focus on identifying qualitatively reported barriers and facilitators to use, and no included studies looked specifically at these factors.

Measuring Implementation and Acceptability in Digital Health Interventions

The high rates of retention and program completion reported from included studies on parenting program chatbots was unexpected given that digital health and mental health interventions generally suffer from low retention rates. While completely digital parenting programs have not been widely studied (refer to the study by Hansen et al [57], which reports retention rates of >70% for in-person interventions that are assisted by technology), a reasonable comparison to a parenting chatbot may be self-guided mental health mobile apps, as they are asynchronous, primarily or totally digital, and interactive. By contrast, Baumel et al [58] reported in a review of 93 mental health mobile apps that the median retention rate after 15 days was 3.9%. In a meta-analysis of 10 randomized controlled trials (n=1090) of digital self-guided interventions for depression, Karyotaki et al [59], found that 40% of participants dropped out before completing 25% of the intervention, and only 17% of the participants completed all the intervention. By contrast, this review reported that, across included studies, 72.8% of participants completed the intervention, which is higher than past reviews of digital health interventions have reported.

There are a few possible explanations for the high retention rates reported in this review. First, implementation and acceptability studies are particularly prone to publication bias, where researchers tend to publish studies with favorable outcomes for publication [60]. Second, compared to other types of digital health interventions that report lower retention, these interventions engaged parents with content primarily about the child and parent-child relationship, rather than solely the parent. This could be more compelling and not provoke the stress and subsequent avoidance associated with self-guided digital health and mental health interventions, which require internal motivation. Third, these interventions took place in high-income settings with onboarding and support from research teams for technical challenges, which could reduce attrition related to difficulty of use, stress, and lack of digital literacy. Finally, these high retention rates could indicate a more fundamental issue with measurements of engagement in digital interventions. Measuring engagement often includes retention, but retention can be measured differently depending on the study design and type of intervention. This lack of standardization in reporting guidelines can promote reporting bias in favor of statistics that indicate greater engagement. Standard measures of engagement, such as response or completion rate, could reduce heterogeneity in reporting. In this review, retention was operationalized variably across studies and did not necessarily align with standard definitions, opting instead for constructs such as program completion or end-survey completion. In some cases, program completion was indicated by not opting out of the chatbot, which may be alternatively described as program enrollment, rather than completion.

Operationalization of engagement also varied, leaving it subject to reporting bias. Some studies measured factors such as the number of interactions, length of responses, or number of modules completed. In contrast, studies limited to SMS text messaging could only track whether participants clicked on embedded links or responded to interactive messages. SMS text messaging–based interventions are also limited in how they track engagement. Links are commonly used to direct participants to a web browser page where engagement can be measured, given that SMS text messaging services lack the same depth of user data collection as mobile as. This highlights how the variability in intervention and study design can impact engagement and, as a result, reporting of retention. The ability to capture engagement data varies by platform; for example, a chatbot embedded in a mobile app can track engagement throughout the digital environment, whereas integrations with existing messaging platforms such as WhatsApp and Facebook Messenger can only collect engagement data as moderated by the platforms themselves. Current literature suggests using multiple valid measures of engagement to build a more complex, multidimensional model of engagement, though this is not always possible with SMS text messaging–delivered interventions. By contrast, trials of in-person parenting programs typically report higher retention rates, though these vary considerably due to barriers associated with in-person delivery [28,61].

Limitations and Strengths

The review also had several limitations. First, the included studies were conducted exclusively in high-income settings, which severely limits the generalizability of these findings to LMICs. Digital literacy, access to consistent cellular service, access to private devices, and privacy concerns disproportionately affect populations in LMIC settings, which many of the included studies did not need to address. Second, the broad inclusion criteria contributed to the significant heterogeneity observed in the types of interventions studied, although some included interventions only marginally met the criteria. Third, the range in study quality may limit the generalizability of the study conclusions. Fourth, the heterogeneity of measurements and small sample size made conducting a meta-analysis impossible. The review also had several strengths. First, it is the first study to review chatbots as a mode for delivering programs that promote family well-being and searched a wide range of databases and gray literature comprehensively. Second, it uses a WoE approach to assess quality and risk of bias, which can more carefully account for study design, intervention design, and study quality when assessing the overall quality of evidence. Third, it compares studies' approaches to measurement to identify how observed heterogeneity might impact reporting and interpretation of findings.

Future Research

There are 3 primary areas of future research related to this study. First, future studies of chatbot-delivered parenting interventions should adopt and adhere to standardized reporting guidelines for digital health interventions such as the mobile health evidence reporting and assessment checklist [62]. Second, further development of guidelines that focus on standardized reporting of feasibility and acceptability measures will allow for between-study comparisons, which is critical for future reviews. Third, future studies should identify barriers to engagement more specifically within the digital environment through collecting additional use data as well as conducting qualitative interviews with participants.

Conclusions

Digital conversational agents as a delivery mechanism for parenting interventions are still in the nascent stages. Significant development is needed in the measurement and reporting of feasibility and acceptability outcomes, as well as in identifying the barriers to and facilitators of engagement with these interventions. This study reviewed the evidence for the feasibility and acceptability of using digital conversational agents to deliver parenting interventions. Given the limited available evidence and its relevancy to the research question, the included studies suggest that digital conversational agents can be a feasible and acceptable way to deliver parenting interventions. A more detailed analysis revealed that considerable heterogeneity in the design of interventions and the measurement of feasibility and acceptability outcomes make comparing findings between studies more challenging and uncertain. However, the overall quality of the findings was moderate, and most of the evidence was in favor of demonstrating feasibility and acceptability. Importantly, these conclusions are drawn from limited evidence. This review highlights the need for more rigorous standardization of reporting on digital interventions, additional research designing and testing new parenting chatbot interventions, and scaling up effectiveness testing of the studies included in this review.
